PRELIMINARY AND INCOMPLETE

## Abstract

We use a Bayesian time-varying parameters structural VAR with stochastic volatility to investigate, for the post-WWII United States, changes in both the reduced-form relationship between vacancies and the unemployment rate, and in their relationship conditional on permanent and transitory output shocks. Evidence points towards both similarities and differences between the Great Recession and the Volcker disinflation, and a widespread time-variation along two key dimensions. First, the slope of the Beveridge curve—as captured by the average cross-spectral gain between vacancies and the unemployment rate at the business-cycle frequencies—has exhibited a large extent of variation since the second half of the 1960s, and a broad pro-cyclical, with the gain being positively correlated with the transitory component of output. The evolution of the slope of the Beveridge curve during the Great Recession appears to have been, so far, very similar to its evolution during the Volcker recession in terms of both its magnitude, and its time-profile. Second, both the Great Inflation episode, and the subsequent Volcker disinflation, have been characterized by a significantly larger (in absolute value) negative correlation between the reduced-form innovations to vacancies and the unemployment rate than the rest of the sample period. Those years also appear to have been characterized by a greater cross-spectral coherence between the two series at the business-cycle frequencies, thus pointing towards them being driven, to a larger extent than the rest of the sample, by common shocks.

JEL CLASSIFICATION: C11, C32, E20, E24,

KEYWORDS: Bayesian VARs; stochastic volatility; time-varying parameters;  
Great Recession; Great Inflation; long-run restrictions

# 1 Introduction

The Beveridge curve describes the relationship between the unemployment rate and open positions, that is, vacancies, in the labor market. Plotting the former against the latter in a scatter diagram results in a downward-sloping relationship that appears to be clustered around a concave curve (see Figure 1). The curve reflects the highly negative correlation between unemployment and vacancies that is a hallmark of labor markets in market economies.

Empirical work on the Beveridge curve has explored the relationship between vacancies and the unemployment rate under the maintained assumption that it can be regarded, as a first approximation, as time-invariant. The behaviour of the two series during the Great Recession, with the unemployment rate seemingly stuck at high levels, even in the presence of a vacancy rate which has been progressively improving, has, however, raised doubts about the meaningfulness of the assumption of time-invariance. This suggests exploring the relationship between the two series allowing for the possibility that it may have evolved over time.

Our paper builds directly on the seminal contribution of Blanchard and Diamond (1989). These authors reintroduced the concept of the Beveridge curve as one of the key relationships in macroeconomic data. They conducted a VAR analysis of unemployment, vacancies, and the labor force in order to identify the driving forces behind movements in the Beveridge curve. We build upon their analysis by identifying both permanent and transitory structural shocks in a time-varying VAR context. By doing so, we are able to trace out the sources of movements, shifts and tilts in the Beveridge curve over time.

The theoretical background for our study, and one that we use for identifying the structural shocks, is the simple search and matching approach to modeling labor markets (see Shimer, 2005). The Beveridge curve specifically encapsulates the logic of this model. In times of economic expansions, unemployment is low and vacancies—that is, open positions offered by firms—are high. Firms want to expand their workforce, but they are unable to do so since the pool of potential employees (that is, the unemployed) is small. As economic conditions slow down and demand slackens, firms post fewer vacancies and unemployment rises, consistent with a downward move along the Beveridge curve. At the trough of the business cycle, firms may have expectations of a future uptick in demand and start posting open positions. This decision is amplified by the large pool of unemployed, which guarantees firms high chances of finding suitable candidates and thus outweighs the incurred

search costs. As the economy improves, unemployment falls and vacancy postings rise in an upward move along the Beveridge curve.

Our empirical analysis starts by documenting the presence of time-variation in the relationship between vacancies and the unemployment rate in the post-WWII United States by means of Stock and Watson's (1996, 1998) time-varying parameters median-unbiased estimation (henceforth, TVP-MUB) methodology, which allows a researcher to test for the presence of random-walk time-variation in the data (against the null of no time-variation). Having detected evidence of random-walk time-variation in the bivariate relationship between vacancies and the unemployment rate, we then use a Bayesian time-varying parameters structural VAR with stochastic volatility to characterize changes over time in the such relationship. Evidence points towards both similarities and differences between the Great Recession and the Volcker disinflation, and widespread time-variation along two key dimensions.

First, the slope of the Beveridge curve, which we capture by the average cross-spectral gain between vacancies and the unemployment rate at business-cycle frequencies, exhibits a large extent of variation since the second half of the 1960s, and a striking counter-cyclicality, with the gain being strongly negatively correlated with the Congressional Budget Office's estimate of the output gap. The evolution of the slope of the Beveridge curve during the Great Recession is very similar to its evolution during the Volcker recession in terms of both its magnitude, and its time-profile. This suggests that the seemingly anomalous behavior of the Beveridge curve during the Great Recession should be met with some caution.

Second, both the Great Inflation episode, and the subsequent Volcker disinflation, are characterized by a significantly larger (in absolute value) negative correlation between the reduced-form innovations to vacancies and the unemployment rate than the rest of the sample period. These years also appear to be characterized by a greater cross-spectral coherence between the two series at the business-cycle frequencies, thus pointing towards them being driven, to a larger extent than the rest of the sample, by common shocks.

Having characterized changes over time in the relationship between vacancies and the unemployment rate, we then proceed, to interpret the previously documented time-varying stylized facts based on an estimated search and matching model. First, we explore, within a simple theoretical model how changes in individual parameters' values affect the relationship between vacancies and the unemployment rate, in order to gauge the origin of the previously documented pattern of variation in the Beveridge relationship.

The paper is organized as follows. The next section presents preliminary evidence on the

presence of (random-walk) time-variation in the bivariate relationship between the vacancy rate and the unemployment rate. Section 3 describes the Bayesian methodology we use to estimate the time-varying parameters VARs with stochastic volatility, whereas Section 4 discusses the evidence of changes over time in the Beveridge relationship. Section 5 describes our structural identification procedure based on insights from a simple search and model, whereby we use both long-run and sign restrictions. We present the results of the structural identification procedure in Section 6. In Section 7 we explore how changes in individual structural parameters of the search and matching model map into corresponding changes in the relationship between vacancies and the unemployment rate. Section 8 concludes.

## 2 Searching for Time Variation in the Beveridge Relationship

Figure 1 presents a time series plot of the unemployment rate and vacancies from 1949 to 2011. The negative comovement between the two series is readily apparent. At the peak of the business cycle unemployment is low and vacancies high. Over the course of a downturn the former rises and the latter declines as fewer and fewer workers are employed and firms have fewer and fewer open positions. The volatility and serial correlation of both series appear of similar magnitude. The second panel in Figure 1 depicts the same series in a scatter plot of vacancies against unemployment, resulting in the well-known downward-sloping relationship that has come to be known as the Beveridge curve. In the graph we identify combinations of unemployment and vacancy rates as belonging to individual business cycles with different colors. Each individual scatter plot starts at the business cycle peak and ends the period before the next peak, as identified by the NBER dates. These peak-to-peak plots thus represent separate Beveridge curves for one business cycle. Visual inspection reveals two observations. First, all curves are downward-sloping, but with different slopes. Second, there is substantial lateral movement in the individual Beveridge curves, ranging from the innermost curve, the 1953-1957 episode, to the outermost, 1982-1990. We take these observations as motivating evidence that the relationship between unemployment and vacancies exhibits substantial variation over time, which a focus on a single aggregate Beveridge curve obscures.

Time variation in data and in theoretical models can take many forms, from continuous variations in unit-root time-varying parameter models to discrete parameter shifts such as in regime-switching frameworks. We regard both discrete and continuous changes as a priori plausible. In this paper, we focus on the latter. As a preliminary step, we provide evidence

of instability in the bivariate relationship between vacancies and unemployment. We apply the methodology developed by Stock and Watson (1996, 1998) to test for the presence of random-walk time-variation in the two-equation VAR representation for the two variables. From an empirical perspective, we prefer their methodology over, for instance, structural break tests for reasons of robustness to uncertainty regarding the specific form of time-variation present in the data. While time-varying parameter models can successfully track processes subject to structural breaks, both Cogley and Sargent (2005) and Benati (2007) show that break tests possess low power when the true data-generation process (DGP) is characterized by random walk time variation. Generally speaking, break tests perform well if the DGP is subject to discrete structural breaks, while TVP models perform well under both scenarios.

The regression model we consider is:

$$x_t = \mu + \alpha(L)V_{t-1} + \beta(L)U_{t-1} + \epsilon_t \equiv \theta'Z_t + \epsilon_t, \quad (1)$$

where  $x_t = V_t, U_t$ , with  $V_t$  and  $U_t$  being the vacancy rate and the unemployment rate, respectively.  $\alpha(L)$  and  $\beta(L)$  are lag polynomials;  $\theta = [\mu, \alpha(L), \beta(L)]'$  and  $Z_t = [1, V_{t-1}, \dots, U_{t-p}]'$ . We select the lag order as the maximum of the lag orders individually chosen by the Akaike, Schwartz, and Hannan-Quinn criteria. Letting  $\theta_t = [\mu_t, \alpha'_t(L), \beta'_t(L)]'$ , the time-varying parameter version of (1) is given by

$$x_t = \theta'_t Z_t + \epsilon_t, \quad (2)$$

$$\theta_t = \theta_{t-1} + \eta_t, \quad (3)$$

with  $\eta_t \sim iid N(0_{4p+1}, \lambda^2 \sigma^2 Q)$ , where  $0_{4p+1}$  is a  $(4p+1)$ -dimensional vector of zeros.  $\sigma^2$  is the variance of  $\epsilon_t$ ,  $Q$  a covariance matrix, and  $E[\eta_t \epsilon_t] = 0$ . Following Stock and Watson (1996, 1998), we set  $Q = [E(Z_t Z_t')]^{-1}$ . Under this normalization, the coefficients on the transformed regressors,  $[E(Z_t Z_t')]^{-1/2} Z_t$ , evolve according to a  $(4p+1)$ -dimensional standard random walk, where  $\lambda^2$  is the ratio between the variance of each transformed innovation and the variance of  $\epsilon_t$ . We estimate the matrix  $Q$  as  $\hat{Q} = \left[ T^{-1} \sum_{t=1}^T z_t z_t' \right]^{-1}$ .

We estimate the specification (1) by OLS, from which we obtain an estimate of the innovation variance,  $\hat{\sigma}^2$ . We then perform an exp- and a sup-Wald joint test for a single unknown break in  $\mu$  and in the sums of the  $\alpha$ 's and  $\beta$ 's, using either the Newey and West (1987) or the Andrews (1991) HAC covariance matrix estimator to control for possible autocorrelation and/or heteroskedasticity in the residuals. Following Stock and Watson (1996), we compute the empirical distribution of the test statistic by considering a 100-point grid of values for  $\lambda$  over the interval  $[0, 0.1]$ . For each element of the grid we compute

the corresponding estimate of the covariance matrix of  $\eta_t$  as  $\hat{Q}_j = \lambda_j^2 \hat{\sigma}^2 \hat{Q}$ ; conditional on  $\hat{Q}_j$  we simulate the model (2)-(3) 10,000 times, drawing the pseudo innovations from pseudo-random *iid*  $N(0, \hat{\sigma}^2)$ . We compute the median-unbiased estimate of  $\lambda$  as that particular value for which the median of the simulated empirical distribution of the test is closest to the test statistic previously computed based on the actual data. Finally, we compute the p-value based on the empirical distribution of the test conditional on  $\lambda_j = 0$ , which we compute based on Bentai (2007)'s extension of the Stock and Watson (1996, 1998) methodology.

We report the estimation results in Table 1. Two main findings emerge. First, there is strong evidence of random-walk time-variation in the equation for the vacancy rate. The p-values for the null of no time-variation ranges from 0.0028 to 0.0195, depending on the specific test statistic. The median-unbiased estimates of  $\lambda$  are comparatively large, between 0.0235 and 0.0327. On the other hand, the corresponding p-values for the unemployment rate are much larger, ranging from 0.1661 to 0.2594, which suggests time-invariance. However, the PDFs of the median-unbiased estimates of  $\lambda$  in Figure 2 paint a more complex picture. Substantial fractions of the probability mass are clearly above zero, while median-unbiased estimates of  $\lambda$  range between 0.0122 and 0.0153. Although, strictly speaking, the null hypothesis of no time-variation cannot be rejected at conventional significance levels in a frequentist sense, the evidence reported in Figure 2 suggests more caution. A more sensible interpretation of the evidence is that all possible values of  $\lambda$  should be regarded, *ex ante*, as equally legitimate. It is the econometrician's task to simply get the more plausible estimate. In what follows we will therefore assume that both equations feature random-walk time-variation. We now proceed to investigate the changing relationship between the vacancy rate and the unemployment rate based on a Bayesian time-varying parameter VAR.

### 3 A Bayesian Time-Varying Parameter VAR with Stochastic Volatility

We define the data vector  $Y_t \equiv [\Delta y_t, V_t, U_t]'$ , where  $\Delta y_t$  is real GDP growth, computed as the log-difference of real GDP;  $V_t$  is the vacancy rate based the Conference Board's Help-Wanted Index and Barnichon's (2010) extension; and  $U_t$  is the unemployment rate. The vacancies and unemployment series are both normalized by the labor force, seasonally adjusted, and converted from the original monthly series by simple averaging. The overall sample period is 1951Q1-2011Q4. We use the first 15 years of data to compute the Bayesian priors, which makes the effective sample period 1965Q1-2011Q4. Appendix A contains a complete description of the data and of their sources.

We specify the following time-varying parameter VAR( $p$ ) model:

$$Y_t = B_{0,t} + B_{1,t}Y_{t-1} + \dots + B_{p,t}Y_{t-p} + \epsilon_t \equiv X_t' \theta_t + \epsilon_t. \quad (4)$$

The notation is standard. As is customary in the literature on Bayesian time-varying parameters VARs, we set the lag order to  $p = 2$ . The time-varying lag coefficients, collected in the vector  $\theta_t$ , are postulated to evolve according to:

$$p(\theta_t \mid \theta_{t-1}, Q) = I(\theta_t) f(\theta_t \mid \theta_{t-1}, Q), \quad (5)$$

where  $I(\theta_t)$  is an indicator function that rejects unstable draws and thereby enforces stationarity on the VAR. The transition  $f(\theta_t \mid \theta_{t-1}, Q)$  is given by:

$$\theta_t = \theta_{t-1} + \eta_t, \quad (6)$$

with  $\eta_t \sim N(0, Q)$ .

We assume that the reduced-form innovations  $\epsilon_t$  in (4) are normally distributed with zero mean, where we factor the time-varying covariance matrix  $\Omega_t$  as:

$$Var(\epsilon_t) \equiv \Omega_t = A_t^{-1} H_t (A_t^{-1})'. \quad (7)$$

The time-varying matrices  $H_t$  and  $A_t$  are defined as:

$$H_t \equiv \begin{bmatrix} h_{1,t} & 0 & 0 \\ 0 & h_{2,t} & 0 \\ 0 & 0 & h_{3,t} \end{bmatrix}, \quad A_t \equiv \begin{bmatrix} 1 & 0 & 0 \\ \alpha_{21,t} & 1 & 0 \\ \alpha_{31,t} & \alpha_{32,t} & 1 \end{bmatrix}. \quad (8)$$

We assume that the  $h_{i,t}$  evolve as geometric random walks,

$$\ln h_{i,t} = \ln h_{i,t-1} + \nu_{i,t}, i = 1, 2, 3. \quad (9)$$

For future reference, we define  $h_t \equiv [h_{1,t}, h_{2,t}, h_{3,t}]'$ . We assume, as in Primiceri (2005), that the non-zero and non-unity elements of the matrix  $A_t$ , which we collect in the vector  $\alpha_t \equiv [\alpha_{21,t}, \alpha_{31,t}, \alpha_{32,t}]'$ , evolve as driftless random walks:

$$\alpha_t = \alpha_{t-1} + \tau_t, \quad (10)$$

where  $\tau_t \sim N(0, S)$ . Finally, we assume that the innovations vector  $[u_t', \eta_t', \tau_t', \nu_t']'$  is distributed as:

$$\begin{bmatrix} u_t \\ \eta_t \\ \tau_t \\ \nu_t \end{bmatrix} \sim N(0, V), \text{ with } V = \begin{bmatrix} I_3 & 0 & 0 & 0 \\ 0 & Q & 0 & 0 \\ 0 & 0 & S & 0 \\ 0 & 0 & 0 & Z \end{bmatrix} \text{ and } Z = \begin{bmatrix} \sigma_1^2 & 0 & 0 \\ 0 & \sigma_2^2 & 0 \\ 0 & 0 & \sigma_3^2 \end{bmatrix}, \quad (11)$$

where  $u_t$  is such that  $\epsilon_t \equiv A_t^{-1} H_t^{\frac{1}{2}} u_t$ .

We follow the literature in imposing a block-diagonal structure for  $V$ , the main reason being parsimony, since the model is already quite heavily parameterized. Allowing for a completely generic correlation structure among different sources of uncertainty would also preclude any structural interpretation of the innovations. Finally, following Primiceri (2005) we adopt the additional simplifying assumption of postulating a block-diagonal structure for  $S$ :

$$S \equiv \text{Var}(\tau_t) = \text{Var}(\tau_t) = \begin{bmatrix} S_1 & 0_{1 \times 2} \\ 0_{2 \times 1} & S_2 \end{bmatrix}, \quad (12)$$

with  $S_1 \equiv \text{Var}(\tau_{21,t})$ , and  $S_2 \equiv \text{Var}([\tau_{31,t}, \tau_{32,t}]')$ . This implies that the non-zero and non-one elements of  $A_t$  belonging to different rows evolve independently. As discussed in Primiceri (2005), this assumption drastically simplifies inference, since it allows Gibbs sampling on the non-zero and non-one elements of  $A_t$  equation by equation.

We estimate (??)-(12) *via* standard Bayesian methods. Appendix B discusses our choices for the priors, and the Markov-Chain Monte Carlo algorithm we use to simulate the posterior distribution of the hyperparameters and the states conditional on the data.

## 4 Reduced-Form Evidence

Figure 3 presents the first set of reduced-form results. It shows time-varying statistics of the estimated innovations in the VAR (4). The first panel depicts the median posterior estimate of the correlation coefficient of the innovations to vacancies and the unemployment rate and associated 68% and 90% coverage regions. The plot shows substantial time variation in this statistic. From the late 1960s to the early 1980s the correlation strengthens from  $-0.4$  to  $-0.85$  before rising (in absolute value) to a low of  $-0.25$ . Over the course of the last decade, the correlation has strengthened again, settling recently close to the average median value of  $-0.55$ . This suggests that the unemployment-vacancy correlation strengthens during periods of broad downturns and high volatility, whereas it weakens in general upswings with low economic turbulence. The evidence over the last decade also supports the impression that the U.S. economy is in a period of a prolonged downswing.<sup>1</sup>

This impression of substantial time variation is strongly supported by second panel which shows the fraction of draws from the posterior distribution for which the correlation coefficient is greater than the average median value over the sample. The fraction of draws

---

<sup>1</sup>We also note that at the same time the coverage regions are tightly clustered around the median estimate during the period of highest instability, namely the last 1970s and the Volcker disinflation, whereas they are more spread out in the beginning and towards the end of the sample.

sinks toward zero at the end of the Volcker disinflation, while it oscillates for much of the Great Moderation between 0.6 and 0.9. Similarly to the results in the first panel, the period since the beginning of the financial crisis in August 2007 is characterized by a substantial decrease in the fraction of draws.

In the third panel of Figure 3, we look at the ratio of the estimated standard deviations of the unemployment and vacancy innovations. The graph shows substantial time variation in this ratio, although overall both innovation variances are of roughly equal size. While the innovation variance of the vacancy rate appears overall dominant, unemployment innovations play a relatively larger role at the end of the Great Inflation, the Volcker disinflation, and the Great Recession. All of these are periods during which the unemployment rate shot up sharply. This suggests a dominant role of specific shocks, namely those tied closely to reduced-form innovations to the unemployment rate, at the onset of an economic downturn. We attempt to identify the sources for this behavior in the following section.

We now narrow our focus on the behavior of unemployment and vacancies at the business-cycle frequencies between 6 quarters and 8 years. We report these results using statistics from the frequency domain. Figure 4 shows median posterior estimates (and associated coverage regions) of the average cross-spectral gain and coherence between the two labor market variables. The gain of a variable  $x_t$  onto another variable  $y_t$  at the frequency  $\omega$  is defined as the absolute value of the OLS-coefficient in the regression of  $y_t$  on  $x_t$  at that frequency, whereas the coherence is the  $R^2$  in that regression. Consequently, the gain has a natural interpretation in terms of the slope of the Beveridge curve, while the coherence measures the fraction of the vacancy-rate's variance at given frequencies that is accounted for by the variation in the unemployment rate. We find it convenient to express time-variation in the Beveridge curve in terms of the frequency domain since it allows us to isolate the fluctuations of interest, namely policy-relevant business cycles, and therefore abstract from secular movements.

Overall, evidence of time-variation is significantly stronger for the gain than for the coherence. As the third panel shows, the coherence between the two series appears to have remained broadly unchanged since the second half of the 1960s, except for a brief run-up during the Great Inflation of the 1970s culminating in the tight posterior distribution during the Volcker disinflation of the early 1980s. Moreover, average coherence is always above 0.8, with 0.9 contained in the 68% coverage region. The high explanatory power of one variable for the other at the business cycle frequencies thus suggests that unemployment and vacancies are driven by a set of common shocks over the sample period.

Panels 1 and 2 of Figure 4 point towards a significant extent of time-variation, whereby the fraction of draws for which the average gain of the unemployment rate onto the vacancy rate is below one oscillates substantially over the sample period. The gain is large during the same periods in which the relative innovation variance of reduced-form shocks to the unemployment rate is large, namely during the first oil shock, the Volcker recession, and the Great Recession. That is, during these recessionary episodes movements in the unemployment rate are relatively larger than those in the vacancy rate. This points towards a flattening of the Beveridge curve in downturns, when small movements in vacancies are accompanied by large movements in unemployment. Time variation in the gain thus captures the shifts and tilts in the individual Beveridge curves highlighted in Figure 1 in one simple statistic.

As a side note, our evidence does not indicate fundamental differences between the Volcker disinflation and the Great Recession, that is between the two deepest recessions in the post-war era. This is especially apparent from the estimated gain in Figure 4 which shows a similar time profile during both episodes. The relationship between vacancies and unemployment, although clearly different from the years leading up to the financial crisis, is broadly in line with that of the early 1980s.

We can now summarize our findings from the reduced-form evidence as follows. The correlation pattern between unemployment and vacancies shows a significant degree of time variation. It strengthens during downturns and weakens in upswings. This is consistent with the idea that over the course of a business cycle, as the economy shifts from a peak to a trough, the labor market moves downward along the Beveridge curve. This movement creates a tight negative relationship between unemployment and vacancies. As the economy recovers, however, vacancies start rising without much movement in unemployment. Hence, the correlation weakens. The economy thus goes off the existing Beveridge curve, in the manner of a counter-clockwise loop, as identified by Blanchard and Diamond (1989), or it moves to a new Beveridge curve, as suggested by the recent literature on mismatch, e.g. Lubik (2012), Furlanetto and Groshenny (2012), Sahin et al. (2012). Evidence from the frequency domain suggests that the same shocks underlie movements in the labor market, but that over the course of the business cycle shocks change in their importance. During recessions movements in unemployment dominate, while in upswings vacancies play a more important role. We now try to identify the structural factors determining this reduced-form behavior.

## 5 Identification

A key focus of our analysis is to identify the underlying sources of the movements in the Beveridge curve. In order to do so we need to identify the structural shocks underlying the behavior of unemployment and vacancies. Our data set contains a nonstationary variable, GDP, and two stationary variables, namely the unemployment and vacancy rates. This allows us to identify one permanent and two transitory shocks from the reduced-form innovation covariance matrix. While the permanent shock has no effect on the two labor market variables in the long-run, it can still lead to persistent movements in these variables, and therefore the Beveridge curve, in the short to medium run.<sup>2</sup> More specifically, we are interested which shocks can be tied to the changing slope and the shifts in the Beveridge curve. We let our identification strategy be guided by the implications of the simple model, which offers predictions for the effects of permanent and transitory productivity shocks as well as for other transitory labor market disturbances.

### 5.1 A Simple Theoretical Framework

We organize the interpretation of our empirical findings around the predictions of the standard search and matching model of the model labor market as described in Shimer (2005). The model is a data-generating process for unemployment and vacancies that is driven by a variety of fundamental shocks.

The model can be reduced to three key equations that will guide our thinking about the empirics. The first equation describes the law of motion for employment:

$$N_t = (1 - \rho_t) \left[ N_{t-1} + m U_{t-1}^\xi V_{t-1}^{1-\xi} \right]$$

Figure 5 depicts the theoretical impulse response functions of the unemployment and vacancy rate to each of the shocks. We can categorize the shocks in two groups, namely into shocks that move unemployment and vacancies in the same direction, and those that imply opposite movements of these variables. This classification underlies the identification by sign restrictions that we use later on in the paper. Both productivity shocks increase vacancies on impact and lower unemployment over the course of the adjustment period. The effect of the temporary shock is much more pronounced since it is calibrated at a much higher level of persistence than the productivity growth rate shock. Persistent productivity shocks increase

---

<sup>2</sup>While this rules out strict hysteresis effects, in the sense that temporary shocks can have permanent effects, it can still lead to behavior that looks over typical sample periods as hysteresis-induced. Moreover, the empirical evidence concerning hysteresis is decidedly mixed.

vacancy posting because they raise the expected value of a filled position. As more vacancies get posted, new employment relationships are established and the unemployment rate falls. We note that permanent shocks have a temporary effect on the labor market because they tilt the expected profit profile in a similar manner to temporary shocks. However, they are identified by their long-run effect on output, which by definition no other shock can muster.

Shocks to match efficiency, vacancy posting costs and unemployment benefits lead to negative comovement between unemployment and benefits. Increases in match efficiency and decreases in the vacancy costs both lower effective vacancy creation cost  $\frac{\kappa_t}{m_t}\theta_t^\xi$  *ceteris paribus* and thereby stimulate initial vacancy creation. These vacancies then lead to lower unemployment over time. In the case of  $\kappa_t$  there is additional feedback from wage setting since the hold-up term  $\kappa_t\theta_t$  can rise or fall. Similarly, increases in match efficiency have an additional effect via the matching function as the higher level of vacancies is now turned into even more new hires, so that employment rises. Movements in benefits also produce negative comovements between the key labor market variables, but the channel is via wage setting. Higher benefits increase the outside option of the worker in bargaining which leads to higher wages. This reduces the expected profit stream to the firm and fewer vacancy postings and higher unemployment.

On the other hand, a persistent increase in the separation rate drives both unemployment and vacancy postings higher. There is an immediate effect on unemployment, which *ceteris paribus* lowers labor market tightness, thereby reducing effective vacancy posting cost. In isolation, this effect stimulates vacancy creation. At the same time, persistent increases in separations reduce expected profit streams from filled positions which has a dampening effect on desired vacancies. This is balanced, however, by persistent declines in tightness because of increased separations. The resulting overall effect is that firms take advantage of the larger pool of potential hires and increase vacancy postings to return to the previous long-run level over time.

Based on the theoretical insights derived above, we now describe how we implement identification of a single permanent shock and two transitory shocks in our time-varying parameter VAR model.

## 5.2 Disentangling Permanent and Transitory Shocks

The permanent shock is identified from a long-run restriction as originally proposed by Blanchard and Quah (1989). We label a shock as permanent if it affects only GDP in the long run, but not the labor market variables. The short- and medium-run effects on all

variables is left unrestricted. In terms of the simple model, the identified permanent shock is consistent with the permanent productivity shock  $A_t^P$  which underlies the stochastic trend in output. We follow the procedure proposed by Galí and Gambetti (2009) for imposing long-run restrictions within a time-varying parameter VAR model. It is based on two alternative rotations of the VAR's covariance matrix of reduced-form innovations.

Let  $\Omega_t = P_t D_t P_t'$  be the eigenvalue-eigenvector decomposition of the VAR's time-varying covariance matrix  $\Omega_t$  in each time period and for each draw from the ergodic distribution. We compute a local approximation to the matrix of the cumulative impulse-response functions (IRFs) to the VAR's structural shocks as:

$$\bar{C}_{t,\infty} = \underbrace{[I_N - B_{1,t} - \dots - B_{p,t}]^{-1}}_{C_0} \bar{A}_{0,t}, \quad (13)$$

where  $I_N$  is the  $N \times N$  identity matrix. The matrix of the cumulative impulse-response functions is then rotated via an appropriate Householder matrix  $H$  in order to introduce zeros in the first row of  $\bar{C}_{t,\infty}$ , which corresponds to GDP, except for the (1,1) entry. Consequently, the first row of the cumulative impulse-response functions,

$$C_{t,\infty}^P = \bar{C}_{t,\infty} H = C_0 \bar{A}_{0,t} H = C_0 A_{0,t}^P \quad (14)$$

is given by  $[x \ 0 \ 0]$ , with  $x$  being a non-zero entry. By definition, the first shock identified by  $A_{0,t}^P$  is the only one exerting a long-run impact on the level of GDP. We therefore label it the permanent output shock. We then consider an alternative rotation of  $\bar{C}_{t,\infty}$  which introduces a zero in the first column of the second and third rows of the matrix of the cumulative impulse-response functions,  $C_{t,\infty}^T = C_0 A_{0,t}^T$ . This implies that the remaining two shocks identified by the matrix  $A_{0,t}^T$  only have a transitory impact on GDP. We therefore label them the transitory shocks.

### 5.3 Identifying the Transitory Shocks Based on Sign Restrictions

We identify the two transitory shocks by assuming that they induce a different impact pattern on vacancies and the unemployment rate. Our theoretical discussion of the search and matching model has shown that a host of shocks, e.g. temporary productivity, vacancy cost, match efficiency shocks, imply negative comovement for the two variables, while separation rate shocks increase vacancies and unemployment on impact. We transfer these insights to the structural VAR identification scheme.

Let  $u_t \equiv [u_t^P, u_t^{T1}, u_t^{T2}]'$  be the vector of the structural shocks:  $u_t^P$  is the permanent output shock,  $u_t^{T1}$  and  $u_t^{T2}$  are the two transitory shocks; let  $u_t = A_{0,t}^{-1} \epsilon_t$ , with  $A_{0,t}$  being

the VAR's structural impact matrix. Our sign restriction approach postulates that  $u_t^{T_1}$  induces the same sign on vacancies and the unemployment rate contemporaneously, while  $u_t^{T_2}$  induces an opposite sign. We compute the time-varying structural impact matrix,  $A_{0,t}$  by combining the methodology proposed by Rubio-Ramirez et al. (2005) for imposing sign restrictions, and the procedure proposed by Galí and Gambetti (2009) for imposing long-run restrictions in time-varying parameter VARs.

Let  $\Omega_t = P_t D_t P_t'$  be the eigenvalue-eigenvector decomposition of the VAR's time-varying covariance matrix  $\Omega_t$ , and let  $\tilde{A}_{0,t} \equiv P_t D_t^{\frac{1}{2}}$ . We draw an  $N \times N$  matrix  $K$  from a standard-normal distribution and compute the  $QR$  decomposition of  $K$ , that is, we find matrices  $Q$  and  $R$  such that  $K = Q \cdot R$ . The intermediate estimate of the time-varying structural impact matrix can then be computed as  $\bar{A}_{0,t} = \tilde{A}_{0,t} \cdot Q'$ . We then compute the local approximation to the matrix of the cumulative IRFs to the VAR's structural shocks,  $\bar{C}_{t,\infty}$ , from (13). In order to introduce zeros in the first row of  $\bar{C}_{t,\infty}$ , we rotate the matrix of the cumulative IRFs via an appropriate Householder matrix  $H$ . The first row of the matrix of the cumulative IRFs,  $C_{t,\infty} = \bar{C}_{t,\infty} H = C_{0,t} \bar{A}_{0,t} H = C_{0,t} A_{0,t}$ , is given by  $[x \ 0 \ 0]$ , with  $x$  being a non-zero entry. If the resulting structural impact matrix  $A_{0,t} = \bar{A}_{0,t} H$  satisfies the sign restrictions we store it. It is discarded otherwise. We then repeat the procedure until we obtain an impact matrix which satisfies both the sign restrictions and the long-run restriction at the same time.

## 6 Structural Evidence

Our identification strategy discussed in section 4 allows us distinguish between one permanent and two transitory shocks. The permanent shock is identified as having a long-run effect on GDP, while the transitory shocks are identified from sign restrictions derived from a simple search and matching model. A side product of our strategy is that we can identify the natural rate of output as its permanent component. Figure 6 shows real GDP in logs together with the median of the posterior distribution of the estimated permanent component and the 68% coverage region. We also report the corresponding transitory component together with the output gap estimate from the Congressional Budget Office (CBO).

Our estimate of the transitory component is most of the times quite close to the CBO output gap, which is produced from a production function approach to potential output, whereas our estimate is largely atheoretical. The main discrepancy between the two estimates is in the wake of the Great Recession, particularly the quarters following the collapse of Lehman Brothers. Whereas the CBO estimate implies a dramatic output shortfall of

around 7.5% of potential output in the first half of 2009, our estimated gap is much less at between 3-4% with little change since then. The reason behind our smaller estimate of the current gap is a comparatively large role played by permanent output shocks in the Great Recession. As the first panel shows, the time profile of the permanent component of log real GDP is estimated to have been negatively affected in a significant way by the Great Recession, with a downward shift in the trend path. That is, natural output is now permanently lower. The question we now investigate is whether and to what extent these trend shifts due to permanent output shocks seep into the Beveridge curve.

## 6.1 Impulse Response Functions

As a first pass, we report impulse response functions (IRFs) to unemployment and vacancies for each of the three shocks in Figures 7-9. Because of the nature of the time-varying parameter VAR, there is not a single IRF for each shock-variable combination. We therefore represent the IRFs by collecting the time-varying coefficients on impact, two quarters ahead, one year ahead, and five years ahead in individual graphs to allow us tracking of how the dynamic behavior of the labor market variables changes over time. An IRF for a specific period can then be extracted by following the impulse response coefficient over the the four panels. The IRFs are normalized such that the long-run effect is attained at a value of one, while transitory shocks eventually return the responses to zero.

In Figure 7, an innovation to the permanent component of output raises GDP on impact by one half of the long-run effect which is obtained fairly quickly after around one year in most periods. A permanent shock tends to raise the vacancy rate on impact, after which it rises for a few quarters before falling to its long-run level. The unemployment rate rises on impact, but then quickly settles around zero. The initial, seemingly counterfactual response is reminiscent of the finding by Galí (1999) that positive productivity shocks have negative employment consequences, which in our model translates into an initial rise in the unemployment rate. Furthermore, the behavior of the estimated impulse responses is broadly consistent with the results from the calibrated theoretical model, both in terms of direction and size of the responses. As we will see below, compared to the transitory shocks the permanent productivity shock, which in the theoretical model takes the form of a growth rate variations exerts only a small effect on unemployment and vacancy rates. Notably, the coverage regions for both variables include zero at all horizons. Overall, the extent of time variation in the IRFs appears small. It is more pronounced at shorter horizons than in the long run.

We report the IRFs to the first transitory shock in Figure 8. This shock is identified as inducing an opposite response of the vacancy and the unemployment rate on impact. In the theoretical model, this identified empirical shock is associated with a transitory productivity shock, variations in match efficiency, hiring costs, or benefit movements. The IRFs of all three variables in the VAR are hump-shaped, with a peak response at one year ahead. Moreover, the amplitudes of the responses are much more pronounced than in the previous case. The vacancy rate is back at its long-run level after 5 years, while there is much more persistence in the unemployment rate and GDP. We also note that our simple theoretical framework cannot replicate this degree of persistence.

The vacancy rate exhibits the highest degree of time variation. What stands out is that its response is asymmetric over the business cycle, but only in the pre-1984 period. During the recessions of the early and mid-1970s, and the deep recession of the early 1980s culminating in the Volcker disinflation, the initial vacancy response declines (in absolute value) over the course of the downturn, before increasing in the recovery phase. That is, the vacancy rate responds less elastically to the first transitory shock during downturns than in expansions - which is not the case for the unemployment rate. This pattern is visible at all horizons. Between the Volcker disinflation and shortly before the onset of the Great Recession the impact response of the vacancy rate declines gradually from -1 to almost -2 percent, before rising again sharply during the recession.

The second transitory shock is identified by imposing the same sign response on unemployment and vacancies. In the context of the theoretical model, such a pattern is due to movements in the separation rate. The IRFs in Figure 9 show that the vacancy rate rises on impact, then reaches a peak four quarters out before returning gradually over the long run. The unemployment rate follows the same pattern, while the shock induces a large negative response of GDP. None of the responses exhibits much time variation, at best there are slow-moving changes in the IRF-coefficients towards less elastic responses. Interestingly, the impact behavior of the vacancy rate declines over the course of the Great Recession. We note, however, that the coverage regions are very wide and include zero for the unemployment rate and GDP at all horizons.

## 6.2 Variance Decompositions

Figure 10 provides evidence on the relative importance of permanent and transitory shocks for fluctuations in vacancies and the unemployment rate. We report the median of the posterior distributions of the respective fractions of innovation variance due to the permanent

shock and the associated coverage regions. For the vacancy rate, permanent shocks appear to play a minor role, with a median estimate of between 10% and 20%. The median estimate for the unemployment rate exhibits a greater degree of variation, oscillating between 10 and 40%. Despite this large extent of time variation, it is difficult to relate fluctuations in the relative importance of permanent shocks to key macroeconomic events. Possible candidates are the period after the first oil shock, when contribution of permanent shocks shot up temporarily, and the long expansion of the 1980s until the late 1990s, which was temporarily punctured by the recession in 1991. Moreover, there is no consistent behavior of the permanent shock contribution over the business cycle. Their importance rises both in downturns and in upswings. On the other hand, this observation gives rise to the idea that all business cycles, at least in the labor market, are different along this dimension.

We now turn to the relative contribution of the two transitory shocks identified by sign restrictions. The evidence is fairly clear-cut. Given the strongly negative unconditional relationship between vacancies and the unemployment rate, we would expect the contribution of  $u_t^{T1}$ , that is, the shock that induces positive contemporaneous co-movement between the two variables, to be small. This is, in fact, borne out by the first column of the graph in Figure 11. The median estimate of the fraction of innovation variance of the two series due to  $u_t^{T1}$  is well below 20%. Correspondingly, the second transitory appears clearly to be dominant for both variables. Based on the theoretical model, we can associate this shock with either temporary productivity disturbances or with stochastic movements in hiring costs, match efficiency or unemployment benefits. Given the parsimonious nature of both the theoretical and empirical model, we cannot further entangle this. The first transitory shock, however, is associated with movements in the separation rate.

### 6.3 Structural Shocks and Beveridge Curve Shifts

We now turn to one of the main findings of the paper, namely the structural sources of time variation in the Beveridge curve. We first discuss the relationship between the business cycle, as identified by the transitory component in GDP and measures of the Beveridge curve. We then decompose the estimated gain and coherence of unemployment and vacancies into their structural components based on the identifying scheme discussed above.

Figure 12 reports two key pieces of evidence on the cyclical behavior of the slope of the Beveridge curve. The left panel shows the fraction of draws from the posterior distribution for which the transitory component of output is positive. This is plotted against the fraction of draws for which the average cross-spectral gain between vacancies and the unemployment

rate at the business-cycle frequencies is greater than one. The graph thus gives an indication of how the slope of the Beveridge curve moves with aggregate activity over the business cycle.

We can differentiate two separate time periods. During the 1970s and the early 1980s, that is, during the Great Inflation, the slope of the Beveridge curve systematically comoves contemporaneously with the state of the business cycle. It is comparatively larger (in absolute value) during business-cycle upswings, and comparatively smaller during periods of weak economic activity. Similarly, the Great Recession is characterized by a very strong co-movement between the slope of the Beveridge curve and the transitory component of output, but this time evidence suggests that the slope slightly leads the business cycle.

On the other hand, in the long expansion period from 1982 to 2008, labelled the Great Moderation and only marred by two minor recessions, the slope of the Beveridge curve comoves less clearly with the business cycle, which is especially apparent during the 1990s. In the early and late part of this sample period the Beveridge curve appears to lag the cycle. This is consistent with the notion of jobless recoveries after the two mild recessions. Despite upticks in economic activity, the labor market did not recover quickly after 1992 and, especially, after 2001. In the data this manifests itself in a large gain between unemployment and vacancies. Moreover, this is also consistent with the changing impulse response patterns to structural shocks discussed above. The outlier in a sense is the Great Recession which resembles more the recessions of the Great Inflation rather than those of the Great Moderation.

The second panel reports additional evidence on the extent of cyclicalities of the slope of the Beveridge curve. It shows the distribution of the slope coefficient in the LAD (Least Absolute Deviations) regression of the cross-spectral gain on a constant and the transitory component of output. Overall, the LAD coefficient is greater than zero for 82.5% of the draws from the posterior distribution, which points towards the pro-cyclicality of the slope of the Beveridge curve.

Figure 13 shows how the two types of shocks shape the evolution of the Beveridge curve. We plot the average gain and coherence between vacancies and the unemployment rate at business-cycle frequencies over time together with the fraction of draws for which the average gain is greater than one. The upper row of the panel reports the statistics conditional on the permanent shock, the lower panel contains those conditional on the two transitory shocks. Whereas the coherence conditional on the permanent shock does not show much time-variation, conditioning on transitory shocks reveals a pattern which is

broadly similar to the reduced-form representation. This suggests that the comparatively greater coherence between the two series around the time of the Great Inflation and of the Volcker disinflation is mostly due to transitory shocks.

Time variation in the gain, on the other hand, appears to be due to both types of shocks. Although the middle column suggests that the extent of statistical significance of the fluctuations in the gain is similar, the first column suggests a different magnitude. In particular, fluctuations in the gain conditional on permanent output shocks, which accounted for a comparatively minor fraction of the innovation variance of the two series, is significantly wider than the corresponding fluctuations conditional on transitory shocks. Moreover, and unsurprisingly in the light of the previously discussed evidence on the relative importance of the two types of shocks, both the magnitude and the time-profile of the fluctuations of the gain conditional on transitory shocks are very close to the reduced-form evidence.

## 7 Interpreting Changes in the Beveridge Curve Based on an Estimated DSGE Model

[Figure 14]

[TO BE COMPLETED]

## 8 Conclusion

In this paper we have used a Bayesian time-varying parameters structural VAR with stochastic volatility to investigate, for the post-WWII United States, changes in both the reduced-form relationship between vacancies and the unemployment rate, and in their relationship conditional on permanent and transitory output shocks. Evidence points towards both similarities and differences between the Great Recession and the Volcker disinflation, and a widespread time-variation along two key dimensions. First, the slope of the Beveridge curve—as captured by the average cross-spectral gain between vacancies and the unemployment rate at the business-cycle frequencies—has exhibited a large extent of variation since the second half of the 1960s, and a broad pro-cyclicality, with the gain being positively correlated with the transitory component of output. The evolution of the slope of the Beveridge curve during the Great Recession appears to have been, so far, very similar to its evolution during the Volcker recession in terms of both its magnitude, and its time-profile. Second, both the Great Inflation episode, and the subsequent Volcker disinflation, have been characterized by a significantly larger (in absolute value) negative correlation between the

reduced-form innovations to vacancies and the unemployment rate than the rest of the sample period. Those years also appear to have been characterized by a greater cross-spectral coherence between the two series at the business-cycle frequencies, thus pointing towards them being driven, to a larger extent than the rest of the sample, by common shocks.

## A The Data

A quarterly seasonally adjusted series for real GDP (‘GDPC96, Real Gross Domestic Product, 3 Decimal, Seasonally Adjusted Annual Rate, Quarterly, Billions of Chained 2005 Dollars’) is from the U.S. Department of Commerce: Bureau of Economic Analysis. A quarterly seasonally adjusted series for the unemployment rate has been computed by converting to the quarterly frequency (by taking averages within the quarter) the series UNRATE (‘Civilian Unemployment Rate, Seasonally Adjusted, Monthly, Percent, Persons 16 years of age and older’), from the U.S. Department of Labor: Bureau of Labor Statistics. A monthly seasonally adjusted series for the vacancy rate has been computed as the ratio between the ‘Help Wanted Index’ (HWI) and the civilian labor force. The HWI index is from the Conference Board up until 1994Q4, and from Barnichon (2010) after that. The labor force series is from the U.S. Department of Labor: Bureau of Labor Statistics (‘CLF16OV, Civilian Labor Force, Persons 16 years of age and older, Seasonally Adjusted, Monthly, Thousands of Persons’). The monthly seasonally adjusted series for the vacancy rate has been converted to the quarterly frequency by taking averages within the quarter.

## B Deconvoluting the Probability Density Function of $\hat{\lambda}$

This appendix describes the procedure we use in section 2 to deconvolute the probability density function of  $\hat{\lambda}$ . To fix ideas, let’s start by considering the construction of a  $(1-\alpha)\%$  confidence interval for  $\hat{\lambda}$ ,  $[\hat{\lambda}_{(1-\alpha)}^L, \hat{\lambda}_{(1-\alpha)}^U]$ , and let’s assume, for the sake of simplicity, that  $\lambda_j$  and  $\hat{\lambda}$  can take any value over  $[0; \infty)$ . Given the duality between hypothesis testing and the construction of confidence intervals, the  $(1-\alpha)\%$  confidence set for  $\hat{\lambda}$  comprises all the values of  $\lambda_j$  that cannot be rejected based on a two-sided test at the  $\alpha\%$  level. Given that an increase in  $\lambda_j$  automatically shifts the PDF of  $\hat{L}_j$  conditional on  $\lambda_j$  upwards,  $\hat{\lambda}_{(1-\alpha)}^L$  and  $\hat{\lambda}_{(1-\alpha)}^U$  are therefore such that

$$P\left(\hat{L}_j > \hat{L} \mid \lambda_j = \hat{\lambda}_{(1-\alpha)}^L\right) = \alpha/2 \quad (\text{B1})$$

$$P\left(\hat{L}_j < \hat{L} \mid \lambda_j = \hat{\lambda}_{(1-\alpha)}^U\right) = \alpha/2 \quad (\text{B2})$$

Let  $\phi_{\hat{\lambda}}(\lambda_j)$  and  $\Phi_{\hat{\lambda}}(\lambda_j)$  be the probability density function and, respectively, the cumulative probability density function of  $\hat{\lambda}$ , defined over the domain of  $\lambda_j$ . The fact that  $[\hat{\lambda}_{(1-\alpha)}^L, \hat{\lambda}_{(1-\alpha)}^U]$  is a  $(1-\alpha)\%$  confidence interval automatically implies that  $(1-\alpha)\%$  of the probability mass of  $\phi_{\hat{\lambda}}(\lambda_j)$  lies between  $\hat{\lambda}_{(1-\alpha)}^L$  and  $\hat{\lambda}_{(1-\alpha)}^U$ . This in turn implies that

$\Phi_{\hat{\lambda}}(\hat{\lambda}_{(1-\alpha)}^L)=\alpha/2$  and  $\Phi_{\hat{\lambda}}(\hat{\lambda}_{(1-\alpha)}^U)=1-\alpha/2$ . Given that this holds for any  $0<\alpha<1$ , we therefore have that

$$\Phi_{\hat{\lambda}}(\lambda_j) = P\left(\hat{L}_j > \hat{L} \mid \lambda_j\right) \quad (\text{B3})$$

In this way, based on the *exp*-Wald test statistic,  $\hat{L}$ , and on the simulated distributions of the  $\hat{L}_j$ 's conditional on the  $\lambda_j$ 's in  $\Lambda$ , we obtain an estimate of the cumulative probability density function of  $\hat{\lambda}$  over the grid  $\Lambda$ , let's call it  $\hat{\Phi}_{\hat{\lambda}}(\lambda_j)$ . Finally, we fit a logistic function to  $\hat{\Phi}_{\hat{\lambda}}(\lambda_j)$  via non-linear least squares and we compute the implied estimate of  $\phi_{\hat{\lambda}}(\lambda_j)$ —call it  $\hat{\phi}_{\hat{\lambda}}(\lambda_j)$ —scaling its elements so that they sum to one.

## C Details of the Markov-Chain Monte Carlo Procedure

We estimate (??)-(??) *via* Bayesian methods. The next two subsections describe our choices for the priors, and the Markov-Chain Monte Carlo algorithm we use to simulate the posterior distribution of the hyperparameters and the states conditional on the data, while the third section discusses how we check for convergence of the Markov chain to the ergodic distribution.

### C.1 Priors

For the sake of simplicity, the prior distributions for the initial values of the states— $\theta_0$  and  $h_0$ —which we postulate all to be normal, are assumed to be independent both from each other, and from the distribution of the hyperparameters. In order to calibrate the prior distributions for  $\theta_0$  and  $h_0$  we estimate a time-invariant version of (??) based on the first 15 years of data, and we set

$$\theta_0 \sim N\left[\hat{\theta}_{OLS}, 4 \cdot \hat{V}(\hat{\theta}_{OLS})\right] \quad (\text{B1})$$

where  $\hat{V}(\hat{\theta}_{OLS})$  is the estimated asymptotic variance of  $\hat{\theta}_{OLS}$ . As for  $h_0$ , we proceed as follows. Let  $\hat{\Sigma}_{OLS}$  be the estimated covariance matrix of  $\epsilon_t$  from the time-invariant VAR, and let  $C$  be its lower-triangular Cholesky factor—i.e.,  $CC' = \hat{\Sigma}_{OLS}$ . We set

$$\ln h_0 \sim N(\ln \mu_0, 10 \times I_N) \quad (\text{B2})$$

where  $\mu_0$  is a vector collecting the logarithms of the squared elements on the diagonal of  $C$ . As stressed by Cogley and Sargent (2002), ‘a variance of 10 is huge on a natural-log scale, making this weakly informative’ for  $h_0$ .

Turning to the hyperparameters, we postulate independence between the parameters corresponding to the two matrices  $Q$  and  $A$ —an assumption we adopt uniquely for reasons of convenience—and we make the following, standard assumptions. The matrix  $Q$  is postulated to follow an inverted Wishart distribution,

$$Q \sim IW(\bar{Q}^{-1}, T_0) \quad (\text{B3})$$

with prior degrees of freedom  $T_0$  and scale matrix  $T_0\bar{Q}$ . In order to minimize the impact of the prior, thus maximizing the influence of sample information, we set  $T_0$  equal to the minimum value allowed, the length of  $\theta_t$  plus one. As for  $\bar{Q}$ , we calibrate it as  $\bar{Q} = \gamma \times \hat{\Sigma}_{OLS}$ , setting  $\gamma = 1.0 \times 10^{-4}$ , the same value used in Cogley and Sargent (2002), and a slightly comparatively ‘conservative’ prior—in the specific sense of allowing ‘little’ random-walk drift—under two respects. First, it is smaller than the value used by Cogley and Sargent (2002),  $\gamma = 3.5 \times 10^{-4}$ . Second—and crucially—it is smaller than the Stock-Watson median-unbiased estimates of the extent of random-walk drift discussed in Section 2, ranging between 0.0235 and 0.0327 for the equation for the vacancy rate, and between 0.0122 and 0.0153 for the equation for the unemployment rate.

As for  $\alpha$ , we postulate it to be normally distributed with a ‘large’ variance,

$$f(\alpha) = N(0, 10000 \cdot I_{N(N-1)/2}). \quad (\text{B4})$$

Finally, as for the variances of the stochastic volatility innovations, we follow Cogley and Sargent (2002, 2005) and we postulate an inverse-Gamma distribution for  $\sigma_i^2 \equiv \text{Var}(\nu_{i,t})$ :

$$\sigma_i^2 \sim IG\left(\frac{10^{-4}}{2}, \frac{1}{2}\right) \quad (\text{B5})$$

## C.2 Simulating the posterior distribution

We simulate the posterior distribution of the hyperparameters and the states conditional on the data *via* the following MCMC algorithm, as found in Cogley and Sargent (2002). In what follows,  $x^t$  denotes the entire history of the vector  $x$  up to time  $t$ —i.e.  $x^t \equiv [x'_1, x'_2, \dots, x'_t]'$ —while  $T$  is the sample length.

(a) *Drawing the elements of  $\theta_t$*  Conditional on  $Y^T$ ,  $\alpha$ , and  $H^T$ , the observation equation (??) is linear, with Gaussian innovations and a known covariance matrix. Following (?), the density  $p(\theta^T | Y^T, \alpha, H^T)$  can be factored as

$$p(\theta^T | Y^T, \alpha, H^T) = p(\theta_T | Y^T, \alpha, H^T) \prod_{t=1}^{T-1} p(\theta_t | \theta_{t+1}, Y^T, \alpha, H^T) \quad (\text{B6})$$

Conditional on  $\alpha$  and  $H^T$ , the standard Kalman filter recursions nail down the first element on the right hand side of (A6),  $p(\theta_T|Y^T, \alpha, H^T) = N(\theta_T, P_T)$ , with  $P_T$  being the precision matrix of  $\theta_T$  produced by the Kalman filter. The remaining elements in the factorization can then be computed via the backward recursion algorithm found, e.g., in (?), or Cogley and Sargent (2005, appendix B.2.1). Given the conditional normality of  $\theta_t$ , we have

$$\theta_{t|t+1} = \theta_{t|t} + P_{t|t}P_{t+1|t}^{-1}(\theta_{t+1} - \theta_t) \quad (\text{B7})$$

$$P_{t|t+1} = P_{t|t} - P_{t|t}P_{t+1|t}^{-1}P_{t|t} \quad (\text{B8})$$

which provides, for each  $t$  from  $T-1$  to  $1$ , the remaining elements in (??),  $p(\theta_t|\theta_{t+1}, Y^T, \alpha, H^T) = N(\theta_{t|t+1}, P_{t|t+1})$ . Specifically, the backward recursion starts with a draw from  $N(\theta_T, P_T)$ , call it  $\tilde{\theta}_T$ . Conditional on  $\tilde{\theta}_T$ , (A7)-(A8) give us  $\theta_{T-1|T}$  and  $P_{T-1|T}$ , thus allowing us to draw  $\tilde{\theta}_{T-1}$  from  $N(\theta_{T-1|T}, P_{T-1|T})$ , and so on until  $t=1$ .

(b) *Drawing the elements of  $H_t$*  Conditional on  $Y^T$ ,  $\theta^T$ , and  $\alpha$ , the orthogonalised innovations  $u_t \equiv A(Y_t - X_t'\theta_t)$ , with  $\text{Var}(u_t) = H_t$ , are observable. Following Cogley and Sargent (2002), we then sample the  $h_{i,t}$ 's by applying the univariate algorithm of (?) element by element.<sup>3</sup>

(c) *Drawing the hyperparameters* Conditional on  $Y^T$ ,  $\theta^T$ ,  $H^T$ , and  $\alpha$ , the innovations to  $\theta_t$  and to the  $h_{i,t}$ 's are observable, which allows us to draw the hyperparameters—the elements of  $Q$  and the  $\sigma_i^2$ —from their respective distributions.

(d) *Drawing the elements of  $\alpha$*  Finally, conditional on  $Y^T$  and  $\theta^T$  the  $\epsilon_t$ 's are observable, satisfying

$$A\epsilon_t = u_t \quad (\text{B9})$$

with the  $u_t$  being a vector of orthogonalized residuals with known time-varying variance  $H_t$ . Following Primiceri (2005), we interpret (B9) as a system of unrelated regressions. The first equation in the system is given by  $\epsilon_{1,t} \equiv u_{1,t}$ , while the following equations can be expressed as transformed regressions as

$$\begin{aligned} \left(h_{2,t}^{-\frac{1}{2}}\epsilon_{2,t}\right) &= -\alpha_{2,1}\left(h_{2,t}^{-\frac{1}{2}}\epsilon_{1,t}\right) + \left(h_{2,t}^{-\frac{1}{2}}u_{2,t}\right) \\ \left(h_{3,t}^{-\frac{1}{2}}\epsilon_{3,t}\right) &= -\alpha_{3,1}\left(h_{3,t}^{-\frac{1}{2}}\epsilon_{1,t}\right) - \alpha_{3,2}\left(h_{3,t}^{-\frac{1}{2}}\epsilon_{2,t}\right) + \left(h_{3,t}^{-\frac{1}{2}}u_{3,t}\right) \end{aligned} \quad (\text{B10})$$

where the residuals are independent standard normal. Assuming normal priors for each equation's regression coefficients the posterior is also normal, and can be computed via equations (77) of (78) in Cogley and Sargent (2005, section B.2.4).

---

<sup>3</sup>For details, see Cogley and Sargent (2005, Appendix B.2.5).

Summing up, the MCMC algorithm simulates the posterior distribution of the states and the hyperparameters, conditional on the data, by iterating on (a)-(d). In what follows, we use a burn-in period of 50,000 iterations to converge to the ergodic distribution, and after that we run 10,000 more iterations sampling every 10th draw in order to reduce the autocorrelation across draws.<sup>4</sup>

## D A Simple Search and Matching Model of the Labor Market

Time is discrete and the time period is a quarter. The model economy is populated by a continuum of identical firms that employ workers, each of whom inelastically supplies one unit of labor. Output  $Y_t$  of a typical firm is linear in employment  $N_t$ :

$$Y_t = A_t N_t. \quad (15)$$

$A_t$  is a stochastic aggregate productivity process. We define its law of motion, and those of the model's other shocks later in the text.

The labor market matching process combines unemployed job seekers  $U_t$  with job openings (vacancies)  $V_t$ . This can be represented by a constant returns matching function,  $M_t = m_t U_t^\xi V_t^{1-\xi}$ , where  $m_t$  is stochastic match efficiency, and  $0 < \xi < 1$  is the (fixed) match elasticity. Unemployment is defined as those workers who are not currently employed:

$$U_t = 1 - N_t, \quad (16)$$

where the labor force is normalized to one. Inflows to unemployment arise from job destruction at rate  $0 < \rho_t < 1$ , which can vary over time. The dynamics of employment are thus governed by the following relationship:

$$N_t = (1 - \rho_t) \left[ N_{t-1} + m_{t-1} U_{t-1}^\xi V_{t-1}^{1-\xi} \right]. \quad (17)$$

This is a stock-flow identity that relates the stock of employed workers  $N_t$  to the flow of new hires  $M_t = m_t U_t^\xi V_t^{1-\xi}$  into employment. The timing assumption is such that once a worker is matched with a firm, the labor market closes. This implies that if a newly hired worker and a firm separate the worker cannot reenter the pool of searchers immediately and has to wait one period before searching again.

---

<sup>4</sup>In this we follow (?). As stressed by (?), however, this has the drawback of ‘increasing the variance of ensemble averages from the simulation’.

The matching function can be used to define the job finding rate, i.e., the probability that a worker will be matched with a firm:

$$p(\theta_t) = \frac{M_t}{U_t} = m_t \theta_t^{1-\xi}, \quad (18)$$

and the job matching rate, i.e., the probability that a firm is matched with a worker:

$$q(\theta_t) = \frac{M_t}{V_t} = m_t \theta_t^{-\xi}, \quad (19)$$

where  $\theta_t = V_t/U_t$  is labor market tightness. From the perspective of an individual firm, the aggregate match probability  $q(\theta_t)$  is exogenous and unaffected by individual decisions. Hence, for individual firms new hires are linear in the number of vacancies posted:  $M_t = q(\theta_t)V_t$ .

A firm chooses the optimal number of vacancies  $V_t$  to be posted and its employment level  $N_t$  by maximizing the intertemporal profit function:

$$E_0 \sum_{t=0}^{\infty} \beta^t [A_t N_t - W_t N_t - \kappa_t V_t], \quad (20)$$

subject to the employment accumulation equation (17). Profits are discounted at rate  $0 < \beta < 1$ . Wages paid to the workers are  $W_t$ , while  $\kappa_t > 0$  is a firm's time-varying cost of opening a vacancy. The first-order conditions are:

$$N_t : \quad \mu_t = A_t - W_t + \beta E_t [(1 - \rho_{t+1})\mu_{t+1}], \quad (21)$$

$$V_t : \quad \kappa_t = \beta q(\theta_t) E_t [(1 - \rho_{t+1})\mu_{t+1}], \quad (22)$$

where  $\mu_t$  is the multiplier on the employment equation.

Combining these two first-order conditions results in the *job creation condition* (JCC):

$$\frac{\kappa_t}{q(\theta_t)} = \beta E_t \left[ (1 - \rho_{t+1}) \left( A_{t+1} - W_{t+1} + \frac{\kappa_{t+1}}{q(\theta_{t+1})} \right) \right]. \quad (23)$$

This captures the trade-off faced by the firm: the marginal effective cost of posting a vacancy,  $\frac{\kappa_t}{q(\theta_t)}$ , that is, the per-vacancy cost  $\kappa$  adjusted for the probability that the position is filled, is weighed against the discounted benefit from the match. The latter consists of the surplus generated by the production process net of wage payments to the workers, plus the benefit of not having to post a vacancy again in the next period.

In order to close the model, we assume in line with the existing literature that wages are determined based on the Nash bargaining solution: surpluses accruing to the matched

parties are split according to a rule that maximizes their weighted average. Denoting the workers' weight in the bargaining process as  $\eta \in [0, 1]$ , this implies the sharing rule:

$$\mathcal{W}_t - \mathcal{U}_t = \frac{\eta}{1 - \eta} (\mathcal{J}_t - \mathcal{V}_t), \quad (24)$$

where  $\mathcal{W}_t$  is the asset value of employment,  $\mathcal{U}_t$  is the value of being unemployed,  $\mathcal{J}_t$  is the value of the marginal worker to the firm, and  $\mathcal{V}_t$  is the value of a vacant job. By free entry,  $\mathcal{V}_t$  is assumed to be driven to zero.

The value of employment to a worker is described by the following Bellman equation:

$$\mathcal{W}_t = W_t + E_t \beta [(1 - \rho_{t+1}) \mathcal{W}_{t+1} + \rho_{t+1} \mathcal{U}_{t+1}]. \quad (25)$$

Workers receive the wage  $W_t$ , and transition into unemployment next period with probability  $\rho_{t+1}$ . The value of searching for a job, when the worker is currently unemployed, is:

$$\mathcal{U}_t = b_t + E_t \beta [p_t (1 - \rho_{t+1}) \mathcal{W}_{t+1} + (1 - p_t (1 - \rho_{t+1})) \mathcal{U}_{t+1}]. \quad (26)$$

An unemployed searcher receives stochastic benefits  $b_t$  and transitions into employment with probability  $p_t (1 - \rho_{t+1})$ . Recall that the job finding rate  $p_t$  is defined as  $p(\theta_t) = M(V_t, U_t)/U_t$  which is decreasing in tightness  $\theta_t$ . It is adjusted for the probability that a completed match gets dissolved before production begins next period. The marginal value of a worker  $\mathcal{J}_t$  is equivalent to the multiplier on the employment equation,  $\mathcal{J}_t = \mu_t$ , so that the respective first-order condition defines the Bellman-equation for the value of a job. Substituting the asset equations into the sharing rule (24) results in the wage equation:

$$W_t = \eta (A_t + \kappa_t \theta_t) + (1 - \eta) b_t. \quad (27)$$

Wage payments are a weighted average of the worker's marginal product  $A_t$ , which the worker can appropriate at a fraction  $\eta$ , and the outside option  $b_t$ , of which the firm obtains the portion  $(1 - \eta)$ . Moreover, the presence of fixed vacancy posting costs leads to a hold-up problem where the worker extracts an additional  $\eta \kappa_t \theta_t$  from the firm.

Finally, I can substitute the wage equation (27) into (23) to derive an alternative representation of the job creation condition:

$$\frac{\kappa_t}{m_t} \theta_t^\xi = \beta E_t (1 - \rho_{t+1}) \left[ (1 - \eta) (A_{t+1} - b_t) - \eta \kappa_t \theta_{t+1} + \frac{\kappa_t}{m_{t+1}} \theta_{t+1}^\xi \right]. \quad (28)$$

Note that this expression is a first-order expectational difference equation in labor market tightness, with productivity and separation rate shocks as driving processes.

## D.1 The Full System

1. Employment equation:

$$N_t = (1 - \rho_t) \left[ N_{t-1} + m_{t-1} U_{t-1}^\xi V_{t-1}^{1-\xi} \right].$$

2. Job-creation condition:

$$\frac{\kappa_t}{m_t} \theta_t^\xi = \beta E_t (1 - \rho_{t+1}) \widehat{A}_{t+1} \left[ A_{t+1}^T - \widehat{W}_{t+1} + \frac{\kappa_{t+1}}{m_{t+1}} \theta_{t+1}^\xi \right]$$

3. Wage equation:

$$\widehat{W}_t = \eta (A_t^T + \kappa_t \theta_t) + (1 - \eta) b_t.$$

4. Unemployment definition:

$$U_t = 1 - N_t$$

5. Tightness definition:

$$\theta_t = \frac{V_t}{U_t}.$$

8. Output:

$$Y_t = A_t A_t^T N_t$$

7. Permanent productivity:

$$\log \widehat{A}_t = \rho_P \log \widehat{A}_{t-1} + \varepsilon_t^P$$

8. Temporary productivity:

$$\log A_t^T = \rho_T \log A_{t-1}^T + \varepsilon_t^T$$

9. Match efficiency:

$$\log m_t = (1 - \rho_m) \log m + \rho_m \log m_{t-1} + \varepsilon_t^m$$

10. Separation rate:

$$\log \rho_t = (1 - \rho_\rho) \log \rho + \rho_\rho \log \rho_{t-1} + \varepsilon_t^\rho$$

11. Vacancy cost:

$$\log \kappa_t = (1 - \rho_\kappa) \log \kappa + \rho_\kappa \log \kappa_{t-1} + \varepsilon_t^\kappa$$

12. Unemployment benefits:

$$\log b_t = (1 - \rho_b) \log b + \rho_b \log b_{t-1} + \varepsilon_t^b$$

Note: the hatted variables  $\widehat{\cdot}$  denote relative to the stochastic trend.

## D.2 Steady State

$$V = \left( \frac{\rho}{1-\rho} \frac{1}{m} \right)^{\frac{1}{1-\xi}} \left( \frac{1-U}{U} \right)^{\frac{1}{1-\xi}} U$$

$$\theta = \frac{V}{U}$$

$$b = \left( 1 - \frac{\eta}{1-\eta} \kappa \theta \right) - \frac{1-\beta(1-\rho)}{\beta(1-\rho)} \frac{1}{1-\eta} \frac{\kappa}{m} \theta^\xi$$

$$N = 1 - U$$

$$\widehat{W} = \eta(1 + \kappa\theta) + (1 - \eta)b$$

## D.3 Linearized System

1. Employment equation:

$$\tilde{N}_t + \frac{\rho}{1-\rho} \tilde{\rho}_t = (1-\rho) \tilde{N}_{t-1} + \rho \xi \tilde{U}_{t-1} + \rho(1-\xi) \tilde{V}_{t-1} + \rho \tilde{m}_{t-1}$$

2. Job-creation condition:

$$\begin{aligned} \beta(1-\rho) \xi \tilde{\theta}_t - \beta(1-\rho) \frac{m}{\kappa} \frac{\widehat{W}}{\theta^\xi} \widetilde{\widehat{W}}_t &= \xi \tilde{\theta}_{t-1} + (1-\beta(1-\rho) \rho_\kappa) \tilde{\kappa}_{t-1} - \\ &\quad - (1-\beta(1-\rho) \rho_m) \tilde{m}_{t-1} + \frac{\rho}{1-\rho} \rho_\rho \tilde{\rho}_{t-1} - \\ &\quad - \rho_P \widetilde{\widehat{A}_{t-1}} - \beta(1-\rho) \frac{m}{\kappa} \theta^{-\xi} \rho_T \tilde{A}_{t-1} + \\ &\quad + \beta(1-\rho) \xi \eta_t^\theta - \beta(1-\rho) \frac{m}{\kappa} \frac{\widehat{W}}{\theta^\xi} \eta_t^W. \end{aligned}$$

3. Wage equation:

$$\widehat{W} \widetilde{\widehat{W}}_t - \eta \kappa \theta \tilde{\theta}_t - \eta \tilde{A}_t^T - \eta \kappa \theta \tilde{\kappa}_t - (1-\eta) b \tilde{b}_t = 0.$$

4. Unemployment definition:

$$\tilde{U}_t + \frac{1-U}{U} \tilde{N}_t = 0$$

5. Tightness definition:

$$\tilde{\theta}_t - \tilde{V}_t + \tilde{U}_t = 0$$

And the rest of the linearized system is just the shocks.
