Abstract

We compute welfare gains from trade in a dynamic, multicountry model with capital accumulation. We examine transition paths for 93 countries following a permanent, uniform, unanticipated trade liberalization. We develop a gradient-free method to compute the exact transition paths in every country. Relative to a static model, the dynamic welfare gains in a model with balanced trade are three times as large. The gains including transition are 60 percent of those computed by comparing only steady states. Trade imbalances have negligible effects on the cross-country distribution of dynamic gains. However, relative to the balanced-trade model, small, less-developed countries accrue the gains faster in a model with trade imbalances by running trade deficits in the short run but have lower consumption in the long-run. In both models, most of the dynamic gains are driven by capital accumulation.

1 Introduction

How large are the welfare gains from trade? This is an old and important question. This question has typically been answered in static settings by computing the change in real income from an observed equilibrium to a counterfactual equilibrium. In such computations, the factors of production and technology in each country are held fixed and the change in real income is entirely due to the change in each country’s trade share that responds to a change in trade frictions. Recent examples include Arkolakis, Costinot, and Rodríguez-Clare (2012) (ACR hereafter), who compute the welfare cost of autarky, and Waugh and Ravikumar (2016), who compute the welfare gains from frictionless trade.

We calculate welfare gains from trade in a dynamic multicountry Ricardian model where international trade affects the capital stock in each period. Our environment is a version of Eaton and Kortum (2002) embedded in a two-sector neoclassical growth model. There is a continuum of tradable intermediate goods. Each country is endowed with an initial stock of capital. Investment goods, produced using tradables, augment the stock of capital.

We calibrate the steady state of the model under balanced trade to reproduce the observed bilateral trade flows across 93 countries. We then conduct a counterfactual exercise in which there is an unanticipated, uniform, and permanent reduction in trade frictions for all countries, and trade is balanced in each period. We compute the exact levels of endogenous variables along the transition path from the calibrated steady state to the counterfactual steady state and calculate the welfare gains using a consumption-equivalent measure as in Lucas (1987).

We find that (i) static calculations understate the gains; in our model, the gains across steady states are five times as large as those in a static model and the dynamic gains with transition are three times as large. (ii) Consumption dynamics are approximately the same across countries except for scale, and the dynamic gain is proportional to the static gain, as in Anderson, Larch, and Yotov (2015). (iii) Comparing only steady states overstates the gains from trade; the dynamic gains accrue gradually and are about 60 percent of steady-state gains for every country. (iv) Both the dynamic gains and the steady-state gains differ across countries: The dynamic gain for Belize is 5 times that of the United States.

In a static model, the gain from trade is typically pinned down by the change in output, which equals the change in measured Total Factor Productivity (TFP). In our model, the change in output is driven by both the change in TFP and the change in capital. In steady state, consumption is proportional to output, so the steady-state welfare gains correspond
to changes in TFP and capital, and are larger than those in a static model. Furthermore, only 20 percent of the steady-state gains are accounted for by the increase in TFP, almost 80 percent of the gains come from the increase in capital. Along the transition, the dynamic path for consumption is determined by an intertemporal Euler equation and consumption is not proportional to output. However, both capital and output increase along the transition path, yielding a higher level of consumption. As a result, dynamic gains are larger than static gains. Since capital accumulates gradually, consumption does not reach its steady-state value instantaneously, so the dynamic gains are lower than the steady-state gains. The dynamics in consumption thus introduce differences between the short-run and the long-run gains from trade as well as differences between static and dynamic gains.

A key assumption in our model is that production of investment goods is more tradables-intensive than production of consumption goods. Trade liberalization reduces the price of investment relative to the price of consumption, which increases the investment rate. Trade liberalization also reduces home trade share which increases TFP. This, in turn, increases the rate of return to capital and, hence, the investment rate. Thus, trade liberalization yields a higher stock of capital, higher output, and higher consumption.

In our model, trade balance in each period limits consumption smoothing since it prevents borrowing and lending across countries. Thus, our gains could be an underestimate. We correct this by allowing countries to buy and sell one-period bonds, thereby endogenizing trade imbalances. A key difference between the two models is that in the model with balanced trade the rate of return to capital differs across countries along the counterfactual transition path, with small (measured by total GDP), less-developed countries having higher returns. Borrowing and lending across countries eliminates the rate of return differences: Resources flow from large, developed countries to small, less-developed countries until the returns are equalized. Small, less-developed countries run a trade deficit in the short run and then converge to a steady state with a trade surplus as they pay down their debt. The opposite is true for large, developed countries.

We consider the same counterfactual reduction in trade frictions as in the model with balanced trade. In the model with trade imbalances, the dynamic welfare gains are almost the same as in the model with balanced trade. In both models, most of the dynamic gains are driven by capital accumulation. In contrast to the model with balanced trade, the rate at which the dynamic gains accrue along the transition in the model with trade imbalances differs across countries. Small, less-developed countries front-load consumption, while large, developed countries do the opposite. Hence, the short-run gains for small, less-developed
countries are larger than those for large, developed countries. The relationship between the rate of capital accumulation and trade imbalances is nonlinear: The rate of accumulation increases exponentially with short-run trade deficits.

We also provide a new and fast computational method for solving multicountry trade models with large state spaces. Our algorithm iterates on a subset of prices using excess demand equations and delivers the entire transition path for 93 countries for the balanced trade model in less than 4 hours on a basic laptop computer (see also (Alvarez and Lucas, 2007)). Note that with one endogenous state variable (e.g., capital stock) taking on just two values in each of the 93 countries, the state space has $2^{93}$ elements. For the model with trade imbalances, the solution takes 40 hours since the state space includes net foreign asset positions as well as capital stocks. Our algorithm uses gradient-free updating rules that are computationally less demanding than the nonlinear solvers used in recent dynamic models of trade (see, e.g., Eaton, Kortum, Neiman, and Romalis, 2016; Kehoe, Ruhl, and Steinberg, 2016).

Our paper is related to recent studies that use “sufficient statistics” to measure changes in welfare by changes in income, which are completely described by changes in the home trade share (ACR). Our balanced-trade model with capital as an endogenous factor of production yields a formula for steady-state gains, in which the change in capital and the change in TFP and, hence, the change in income, are fully characterized by the change in home trade share. However, our formula is not valid along the transition path since (i) consumption is not proportional to income and (ii) the home trade share changes immediately whereas consumption changes gradually along with capital and output.

Our paper is also related to three papers on multi-country models with capital accumulation: Alvarez and Lucas (2016), Eaton, Kortum, Neiman, and Romalis (2016), and Anderson, Larch, and Yotov (2015).\(^1\) Alvarez and Lucas (2016) approximate the dynamics in a model with balanced trade by linearizing around the steady state; our computational method provides an exact dynamic path. The linear approximation might be inaccurate for computing transitional dynamics in cases of large trade liberalizations. For instance, we find that the dynamic gain for the median-gain country increases exponentially with reductions in trade frictions.

Eaton, Kortum, Neiman, and Romalis (2016) compute the counterfactuals by solving the planner’s problem. In their computation, each country’s share in world consumption

\(^1\)Baldwin (1992) and Alessandria, Choi, and Ruhl (2014) study welfare gains in two-country models with capital accumulation and balanced trade (see also Brooks and Pujolas, 2016).
expenditures is the same in the benchmark and in the counterfactual since the Pareto weight for each country is its share. Instead, we solve for the competitive equilibrium and find that each country’s share in world consumption expenditures changes in the counterfactual. For example, Belize’s share increases by a factor of 3 across steady states, whereas the U.S.’s share decreases.

Anderson, Larch, and Yotov (2015) compute transitional dynamics in a model where the relative price of investment and the investment rate do not depend on trade frictions. The investment rate can be computed once and for all as a constant pinned down by the structural parameters. The transition path can then be computed as a solution to a sequence of static problems. In our model, the current allocations and prices depend on the entire path of prices and trade frictions. Hence, we have to simultaneously solve a system of second-order, non-linear difference equations. Quantitatively, the increase in investment rate for the country with the median gain is 81 percent across steady states in our model. This is consistent with the evidence in Wacziarg and Welch (2008) who show that for 118 countries, gross domestic product (GDP) and the investment rate increase after trade liberalization as in our model. Furthermore, Wacziarg (2001) finds that trade increases GDP primarily through an increase in investment, as in our model.

The rest of the paper proceeds as follows. Section 2 presents the model with balanced trade. Section 3 describes the calibration while Section 4 reports the results from the counterfactual exercise. Section 5 explores the quantitative implications in the model with endogenous trade imbalances, and Section 6 concludes.

2 Model

There are $I$ countries indexed by $i = 1, \ldots, I$ and time is discrete, running from $t = 1, \ldots, \infty$. There are three sectors: consumption, investment, and intermediates, denoted by $c$, $x$, and $m$, respectively. Neither consumption goods nor investment goods are tradable. There is a continuum of intermediate varieties that are tradable. Production of all goods is carried out by perfectly competitive firms. As in Eaton and Kortum (2002), each country’s efficiency in producing each intermediate variety is a realization of a random draw from a country-specific distribution. Trade in intermediate varieties is subject to iceberg costs. Each country purchases each intermediate variety from its lowest-cost supplier and all of the varieties are aggregated into a composite intermediate good. The composite good is used as an input along with capital and labor to produce the consumption good, the investment good, and
the intermediate varieties.

Each country has a representative household. The household owns its country’s stock of capital and labor, which it inelastically supplies to domestic firms, and purchases consumption and investment goods from the domestic firms. We assume that trade is balanced in each period; we endogenize trade imbalances in Section 5.

2.1 Endowments

The representative household in country $i$ is endowed with a labor force of size $L_i$ in each period and an initial stock of capital, $K_{i1}$.

2.2 Technology

There is a unit interval of varieties in the intermediates sector. Each variety within the sector is tradable and is indexed by $v \in [0, 1]$.

**Composite good** Within the intermediates sector, all of the varieties are combined with constant elasticity to construct a sectoral composite good according to

$$M_{it} = \left[ \int_0^1 q_{it}(v)^{1-1/\eta} dv \right]^{\eta/(\eta-1)},$$

where $\eta$ is the elasticity of substitution between any two varieties. The term $q_{it}(v)$ is the quantity of good $v$ used by country $i$ to construct the composite good at time $t$ and $M_{it}$ is the quantity of the composite good available in country $i$ to be used as an input.

**Varieties** Each variety is produced using capital, labor, and the composite good. The technologies for producing each variety are given by

$$Y_{mit}(v) = z_{mi}(v) \left( K_{mit}(v)^{\alpha} L_{mit}(v)^{1-\alpha} \right)^{\nu_m} M_{mit}(v)^{1-\nu_m}.$$  

The term $M_{mit}(v)$ denotes the quantity of the composite good used by country $i$ as an input to produce $Y_{mit}(v)$ units of variety $v$, while $K_{mit}(v)$ and $L_{mit}(v)$ denote the quantities of capital and labor used. The parameter $\nu_m \in [0, 1]$ denotes the share of value added in total.

---

2Caliendo, Dvorkin, and Parro (2015) develop a trade model with many sectors, regions, and countries, where there is no capital but labor is mobile across regions and sectors. They study the effects of increased competition from China on U.S. labor markets. The dynamics in their paper are driven by labor mobility.
output and $\alpha$ denotes capital’s share in value added. These parameters are constant across countries and over time.

The term $z_{mi}(v)$ denotes country $i$’s productivity for producing variety $v$. Following Eaton and Kortum (2002), the productivity draw comes from independent Fréchet distributions with shape parameter $\theta$ and country-specific scale parameter $T_{mi}$, for $i = 1, 2, \ldots, I$. The c.d.f. for productivity draws in country $i$ is $F_{mi}(z) = \exp(-T_{mi}z^{-\theta})$.

In country $i$ the expected value of productivity is $\gamma - \frac{1}{\theta} T_{1} T_{mi}$, where $\gamma = \Gamma(1 + \frac{1}{\theta}(1 - \eta))^{\frac{1}{1-\eta}}$ and $\Gamma(\cdot)$ is the gamma function, and $T_{1} T_{mi}$ is the fundamental productivity in country $i$. If $T_{mi} > T_{mj}$, then on average, country $i$ is more efficient than country $j$ at producing intermediate varieties. A smaller $\theta$ implies more room for specialization and, hence, more gains from trade.

**Consumption good** Each country produces a final consumption good using capital, labor, and intermediates according to

$$Y_{cit} = A_{ci} (K_{cit}^{\alpha} L_{cit}^{1-\alpha})^{\nu_c} M_{cit}^{1-\nu_c}.$$  

The terms $K_{cit}$, $L_{cit}$, and $M_{cit}$ denote the quantities of capital, labor, and the composite good used by country $i$ to produce $Y_{cit}$ units of consumption at time $t$. The parameters $\alpha$ and $\nu_c$ are constant across countries and over time. The term $A_{ci}$ captures country $i$’s productivity in the consumption goods sector—this term varies across countries.

**Investment good** Each country produces an investment good using capital, labor, and intermediates according to

$$Y_{xit} = A_{xi} (K_{xit}^{\alpha} L_{xit}^{1-\alpha})^{\nu_x} M_{xit}^{1-\nu_x}.$$  

The terms $K_{xit}$, $L_{xit}$, and $M_{xit}$ denote the quantities of capital, labor, and the composite good used by country $i$ to produce $Y_{xit}$ units of investment at time $t$. The parameters $\alpha$ and $\nu_x$ are constant across countries and over time. The term $A_{xi}$ captures country $i$’s productivity in the investment goods sector—this term varies across countries. Note that when $\nu_x = \nu_c$ the relative price of investment is pinned down by the relative productivities.
2.3 Trade

International trade is subject to frictions that take the iceberg form. Country $i$ must purchase $d_{ij} \geq 1$ units of any intermediate variety from country $j$ in order for one unit to arrive; $d_{ij} - 1$ units melt away in transit. As a normalization, we assume that $d_{ii} = 1$ for all $i$.

2.4 Preferences

The representative household’s lifetime utility is given by

$$\sum_{t=1}^{\infty} \beta^{t-1} L_i \left( \frac{C_{it}/L_i}{1-1/\sigma} \right)^{1-1/\sigma},$$

where $C_{it}/L_i$ is consumption per capita in country $i$ at time $t$, $\beta \in (0, 1)$ denotes the period discount factor and $\sigma$ denotes the intertemporal elasticity of substitution. Both parameters are constant across countries and over time.

Capital accumulation The representative household enters period $t$ with $K_{it}$ units of capital, which depreciates at the rate $\delta$. Investment, $X_{it}$, adds to the stock of capital.

$$K_{it+1} = (1 - \delta)K_{it} + X_{it}.$$ 

Budget constraint The representative household earns income by supplying capital and labor inelastically to domestic firms earning a rental rate $r_{it}$ on capital and a wage rate $w_{it}$ on labor. The household purchases consumption at the price $P_{cit}$ and purchases investment at the price $P_{xit}$. The budget constraint is given by

$$P_{cit}C_{it} + P_{xit}X_{it} = r_{it}K_{it} + w_{it}L_i.$$ 

2.5 Equilibrium

A competitive equilibrium satisfies the following conditions: (i) taking prices as given, the representative household in each country maximizes its lifetime utility subject to its budget constraint and technology for accumulating capital, (ii) taking prices as given, firms maximize profits subject to the available technologies, (iii) intermediate varieties are purchased from their lowest-cost provider subject to the trade frictions, and (iv) all domestic markets clear and trade is balanced in each period. At each point in time, we take world GDP as the
numéraire: \( \sum_i r_{it} K_{it} + w_{it} L_i = 1 \) for all \( t \). We describe each equilibrium condition in more detail in Appendix A.

### 2.6 Welfare Gains

We measure changes in welfare using consumption equivalent units as in Lucas (1987). In static models these changes are equal to changes in income since consumption equals income. In our model, consumption is proportional to income in steady state and the ratio of consumption to income, \( 1 - \frac{\alpha \delta}{\beta - (1 - \delta)} \), is the same across countries.

We measure the steady-state gains in country \( i \), \( \lambda_{i}^{ss} \), according to:

\[
1 + \frac{\lambda_{i}^{ss}}{100} = \frac{C_{i}^{**}}{C_{i}^{*}} = \frac{y_{i}^{**}}{y_{i}^{*}},
\]

where \( C_{i}^{*} \) and \( y_{i}^{*} \) are the consumption and per capita income in the initial steady state in country \( i \) and \( C_{i}^{**} \) and \( y_{i}^{**} \) are the consumption and per capita income in the counterfactual steady state in country \( i \).

Along the transition path, consumption might not be proportional to income. The dynamic gain in country \( i \) is measured by \( \lambda_{i}^{dyn} \) that solves:

\[
\sum_{t=1}^{\infty} \beta^{t-1} L_i \left( \frac{\left( 1 + \frac{\lambda_{i}^{dyn}}{100} \right) C_{i}^{*}}{L_i} \right)^{1-1/\sigma} = \sum_{t=1}^{\infty} \beta^{t-1} L_i \left( \frac{\bar{C}_{it}}{L_i} \right)^{1-1/\sigma},
\]

where \( \bar{C}_{it} \) is the consumption at time \( t \) in the counterfactual. Note that in steady state, \( \bar{C}_{it} \) is constant over time and equation (2) collapses to equation (1).

Computing the dynamic gains requires computing the transition path for consumption, which depends on the path for income. We define real income per capita in our model as \( y_{it} \equiv \frac{r_{it} K_{it} + w_{it} L_i}{K_{it} L_i} \). In Appendix D we show that

\[
y_{it} \propto A_{i} \left( \frac{T_{mi}}{\pi_{iit}} \right)^{\frac{1-\nu_c}{\nu_m}} \left( \frac{K_{it}}{L_i} \right)^{\alpha}
\]

Trade liberalization results in an immediate and permanent drop in the home trade shares and, hence, permanently higher measured TFP on impact. The increase in TFP yields a higher rate of return to capital, which increases the investment rate. The optimal investment rate is governed by the intertemporal Euler equation that determines the consumption path:
\[
\frac{C_{it+1}}{C_{it}} = \beta^\sigma \left( 1 + \frac{r_{it+1}}{P_{xit+1}} - \delta \right)^\sigma \left( \frac{P_{xit+1}/P_{cit+1}}{P_{xit}/P_{cit}} \right)^\sigma.
\] (4)

Capital stock does not change on impact, but it increases gradually along the transition path. The rate of accumulation depends on the relative price of investment given by

\[
\frac{P_{xit}}{P_{cit}} \propto \left( \frac{A_{ci}}{A_{xi}} \right) \left( \frac{T_{mi}}{\pi_{iti}} \right)^{\frac{\nu_{x} - \nu_{c}}{\theta \nu_{m}}}.
\] (5)

The lower home trade share implies a lower relative price of investment since \(\nu_x < \nu_c\), so it is feasible to allocate a larger share of income to investment without sacrificing consumption.

Combining the Euler equation with the budget constraint and the capital accumulation technology, the equilibrium law of motion for capital must obey the following equation in every country:

\[
\left( 1 + \frac{r_{it+1}}{P_{xit+1}} - \delta \right) \left( \frac{P_{xit+1}}{P_{cit+1}} \right) K_{it+1} + \left( \frac{w_{it+1}}{P_{cit+1}} \right) L_i - \left( \frac{P_{xit+1}}{P_{cit+1}} \right) K_{it+2}
\]

\[
= \beta^\sigma \left( 1 + \frac{r_{it+1}}{P_{xit+1}} - \delta \right)^\sigma \left( \frac{P_{xit+1}/P_{cit+1}}{P_{xit}/P_{cit}} \right)^\sigma
\]

\[
\times \left[ \left( 1 + \frac{r_{it}}{P_{xit}} - \delta \right) \left( \frac{P_{xit}}{P_{cit}} \right) K_{it} + \left( \frac{w_{it}}{P_{cit}} \right) L_i - \left( \frac{P_{xit}}{P_{cit}} \right) K_{it+1} \right].
\] (6)

Note that the dynamics of capital in country \(i\) depend on the capital stocks in all other countries due to trade. The dynamics are pinned down by the solution to a system of \(I\) simultaneous, second-order, nonlinear difference equations. The optimality conditions for the firms combined with the relevant market clearing conditions and trade balance pin down the prices as a function of the capital stocks in all countries.

Equation (6) also reveals that a change in trade friction for any country at any point in time affects the dynamic path of all countries.

### 3 Calibration

We calibrate the parameters of the model to match several observations in 2011. We assume that the world is in steady state in 2011. Table C.1 provides the equilibrium conditions that describe the steady state. The only exogenous difference between the initial steady state and the counterfactual steady state is the value of the trade costs \(d_{ij}\). Both steady states can be
computed without knowing the transition paths.\footnote{For the model with trade imbalances the steady state depends on the transition path. See Section 5 for details on computation.} Our technique for computing the steady state is standard, while our method for computing the transition path between steady states is new.

Our data covers 93 countries (containing 91 individual countries plus 2 regional country groups). Table F.1 in the appendix provides a list of the countries. This list accounts for 90 percent of world GDP as measured by the Penn World Tables version 8.1 (Feenstra, Inklaar, and Timmer, 2015, hereafter PWT 8.1) and for 84 percent of world trade in manufactures as measured by the UN Comtrade Database. Appendix B provides the details of our data.

### 3.1 Common parameters

The values for the common parameters are reported in Table 1. We use recent estimates of the trade elasticity by Simonovska and Waugh (2014) and set $\theta = 4$. We set $\eta = 2$ which satisfies the condition $1 + \frac{1}{\theta}(1 - \eta) > 0$. This value plays no quantitative role in our results.

</tr>
</tbody>
</table>

We set the share of capital in value added to $\alpha = 0.33$ (Gollin, 2002), the discount factor to $\beta = 0.96$, so that the steady-state real interest rate is about 4 percent, and the intertemporal elasticity of substitution to $\sigma = 0.67$.

We compute $\nu_m = 0.28$ by taking the cross-country average of the ratio of value added to gross output of manufactures. We compute $\nu_x = 0.33$ by taking the cross-country average of the ratio of value added to gross output of investment goods.

Computing $\nu_c$ is slightly more involved since there is no clear industry classification for consumption goods. Instead, we infer this share by interpreting the national accounts
through the lens of our model. We begin by noting that by combining firm optimization and market clearing conditions for capital and labor we get

$$r_i K_i = \frac{\alpha}{1 - \alpha} w_i L_i.$$  \hfill (7)

In steady state, the Euler equation and the capital accumulation technology imply

$$P_{xi} X_i = \frac{\delta \alpha}{\beta - (1 - \delta)} \frac{w_i L_i}{1 - \alpha} = \phi_x \frac{w_i L_i}{1 - \alpha}.$$  \hfill (8)

We compute $\phi_x$ by taking the cross-country average of the share of gross fixed capital formation in nominal GDP. The household’s budget constraint then implies that

$$P_{ci} C_i = \frac{w_i L_i}{1 - \alpha} - P_{xi} X_i = (1 - \phi_x) \frac{w_i L_i}{1 - \alpha}.  \hfill (9)$$

Consumption in our model corresponds to the sum of private and public consumption, changes in inventories, and net exports. We use the trade balance condition together with the firm optimality and the market clearing conditions for sectoral output to obtain

$$P_{mi} M_i = [(1 - \nu_x) \phi_x + (1 - \nu_c)(1 - \phi_x)] \frac{w_i L_i}{1 - \alpha} + (1 - \nu_m) P_{mi} M_i, \hfill (10)$$

where $P_{mi} M_i$ is total absorption of manufactures in country $i$ and $\frac{w_i L_i}{1 - \alpha}$ is the nominal GDP. We back out $\nu_c$ from equation (8).

Given the value of $\phi_x$ and the relation $\phi_x = \frac{\delta \alpha}{\beta - (1 - \delta)}$, the depreciation rate for capital is $\delta = 0.06$.

3.2 Country-specific parameters

We set the workforce, $L_i$, equal to the population in country $i$ documented in PWT 8.1. The remaining parameters $A_{xi}, T_{mi}, A_{xi}$, and $d_{ij}$, for $(i, j) = 1, \ldots, I$, are not directly observable. We back these out by linking steady-state relationships of the model to observables.

The equilibrium structure relates the unobserved trade frictions between any two countries to the ratio of intermediate goods prices in the two countries and the trade shares:

$$\frac{\pi_{ij}}{\pi_{jj}} = \left(\frac{P_{mj}}{P_{mi}}\right)^{-\theta} d_{ij}^{-\theta}. \hfill (11)$$

Appendix B describes how we construct the empirical counterparts to prices and trade shares.
For observations in which $\pi_{ij} = 0$, we set $d_{ij} = 10^8$. We also set $d_{ij} = 1$ if the inferred value of trade cost is less than 1.

We use three structural relationships to pin down the productivity parameters $A_{ci}, T_{mi},$ and $A_{xi}$:

$$
\frac{P_{ci}}{P_{mi}} = \frac{P_{cU}}{P_{mU}} = \left( \frac{T_{mi}^{\frac{1}{\theta}}}{\pi_{ii}} \right)^{\frac{1}{\theta}} \frac{A_{ci}}{A_{cu}} \left( \frac{T_{mi}^{\frac{1}{\theta}}}{\pi_{ii}} \right)^{\frac{1}{\theta}} \frac{\nu_{m} - \nu_{c}}{\nu_{m}} \nu_{c} \right)
$$

Equations (10)–(12) are derived in Appendix D. The three equations relate observables—the price of consumption relative to intermediates, the price of investment relative to intermediates, income per capita, and home trade shares—to the three unknown productivity parameters. We set $A_{cU} = T_{mU} = A_{xU} = 1$ as a normalization, where the subscript $U$ denotes the United States. For each country $i$, system (10)–(12) has three nonlinear equations with three unknowns: $A_{ci}, T_{mi},$ and $A_{xi}$. Information about constructing the empirical counterparts to $P_{ci}, P_{mi}, P_{xi}, \pi_{ii}$ and $y_i$ is in Appendix B.

These equations are quite intuitive. The expression for income per capita provides a measure of aggregate productivity across all sectors: Higher income per capita is associated with higher productivity levels, on average. The expressions for relative prices boil down to two components. The first term reflects something akin to the Balassa-Samuelson effect: All else equal, a higher price of capital relative to intermediates suggests a low productivity in capital goods relative to intermediate goods. In our setup, the measured productivity for intermediates is endogenous, reflecting the degree of specialization as captured by the home trade share. The second term reflects the relative intensity of intermediate inputs. If measured productivity is high in intermediates, then the price of intermediates is relatively low and the sector that uses intermediates more intensively will have a lower relative price.
3.3 Model fit

Our model consists of 8,832 country-specific parameters: \( I(I - 1) = 8,556 \) bilateral trade frictions, \( I - 1 = 92 \) consumption-good productivity terms, \( I - 1 = 92 \) investment-good productivity terms, and \( I - 1 = 92 \) intermediate-goods productivity terms.

Calibration of the country-specific parameters uses 8,924 data points. The trade frictions use up \( I(I - 1) = 8,556 \) data points for bilateral trade shares and \( I - 1 = 92 \) for the ratio of absolute prices of intermediates. The productivity parameters use up \( I - 1 = 92 \) data points for the price of consumption relative to intermediates, \( I - 1 = 92 \) data points for the price of investment relative to intermediates, and \( I - 1 = 92 \) data points for income per capita.

The model matches the targeted data well. The correlation between model and data is 0.96 for the bilateral trade shares (see Figure 1), 0.97 for the absolute price of intermediates, 1.00 for income per capita, 0.96 for the price of consumption relative to intermediates, and 0.99 for the price of investment relative to intermediates.

Figure 1: Model fit for bilateral trade share

![Graph](image)

Notes: Horizontal axis, data; Vertical axis, model.

We use prices of consumption and investment, relative to intermediates, in our calibration. The correlation between the model and the data is 0.93 for the absolute price of consumption and 0.97 for the absolute price of investment. The correlation for the price of investment
Figure 2: Model fit for capital-labor ratio and investment rate

(a) Capital-labor ratio

(b) Investment rate

Notes: Horizontal axis, data; Vertical axis, model.

relative to consumption is 0.95.

Our theory has implications also for the (untargeted) cross-country differences in capital and investment rates. Figure 2 shows that the model matches the data on capital-labor ratios; the correlation is 0.93. It also shows that our model is broadly consistent with the real investment rate, $\frac{X}{y_L}$. The nominal investment rate, $\frac{P_x X}{P_c y_L}$ is the same across countries in the steady state and is equal to 19.5 percent; in the data, it is 23.3 percent on average, and uncorrelated with economic development.

4 Counterfactuals

In this section, we implement a counterfactual trade liberalization via an unanticipated, uniform, and permanent reduction in trade frictions. The world begins in the calibrated steady state. At the beginning of period $t = 1$, trade frictions fall uniformly in all countries such that the ratio of world trade to GDP increases from 50 percent in the calibrated steady state to 100 percent in the new steady state. This amounts to reducing $d_{ij} - 1$ by 55 percent for each country pair $i, j$. All other parameters are fixed at their calibrated values.
4.1 Computing the transition path

To compute the transition path, we begin by reducing the infinite horizon problem down to a finite time model with \( t = 1, \ldots, T \) periods. We make \( T \) sufficiently large to ensure convergence to a new steady state; \( T = 85 \) proved sufficient in our computations. We first solve for a terminal steady state to use as a boundary condition for the path of capital stocks (this does not require knowing \( T \) or the transition path). The other boundary condition is the set of capital stocks in the calibrated steady state; the transition path starts from this set. We guess the entire sequence of wages and rental rates in every country \((93 \times T \text{ wages and } 93 \times T \text{ rental rates})\). Given the wages and rental rates, we recover all remaining prices and trade shares using optimality conditions for firms, then solve for the optimal sequence of consumption and investment in every country using the intertemporal Euler equation. Finally, we use deviations from domestic market clearing and trade balance conditions to update the sequences of wages and rental rates. We continue the process until we reach a fixed point where all markets clear in all periods. Appendix C describes our solution method in more detail.

The main challenge in solving dynamic multicountry trade models is the curse of dimensionality. For instance, our intertemporal Euler equation is a second order and nonlinear equation for capital in every country. In closed economies or two-country models, recursive methods such as value function iteration or policy function iteration can be employed efficiently by discretizing the state space for capital stocks in each country. In our world with 93 countries, \( n \) discrete values for capital stock would imply \( n^{93} \) grid points in the state space. An alternative is to use recent advances in shooting algorithms that involve iterating on guesses for the entire path of capital in every country. Each iteration involves computing gradients to update the entire path of capital. With \( T \) periods and 93 countries, the updates require \( 93 \times T \) gradients and each gradient requires solving the entire model.

Our method relies on two excess demands to update all \( 93 \times T \) wages and rental rates. If country \( i \) has positive net exports at time \( t \) we increase the wage in \( i \) at time \( t \). The size of net exports determines the magnitude of the increase in wage. If country \( i \) has an excess demand for capital, we increase the rental rate in \( i \). Such updates are done for all \( 93 \times T \) wages and rental rates simultaneously, so we bypass the costly computation of gradients. We can compute the entire transition path in less than 4 hours on a basic laptop computer.
4.2 Welfare gains from trade

We compute the steady-state gains from trade using equation (1) and the dynamic gains from trade using equation (2).\footnote{We calculate sums in (2) using the counterfactual transition path from \(t = 1, \ldots, 150\) and setting the counterfactual consumption equal to the new steady-state level of consumption for \(t = 151, \ldots, 400\).}

**Steady-state gains** The steady-state gains vary substantially across countries, ranging from 18 percent for the United States to 92 percent for Belize (Figure 3a). The median gain (Greece) is 53 percent.

Recall that consumption is proportional to income in steady state, so in equation (1) consumption can be replaced by income and the welfare gain can be measured by change in per capita income. Steady-state income per capita in country \(i\) can be expressed as

\[
y_i \propto A \left( \frac{T_{mi}}{\pi_{ii}} \right)^{1-\nu_c} \left( \frac{T_{mi}}{\pi_{ii}} \right)^{\alpha (1-\nu_x)} \left(1 - \alpha \theta \nu_m \right)^{\nu_c (1-\nu_x)}.
\]

(13)

The constant of proportionality is not country-specific. (See Appendix D for the derivation.) In equation (13), \(\pi_{ii}\) in the calibrated steady state is the observed home trade share and \(\pi_{ii}\) in the counterfactual steady state with lower trade frictions is computed by solving the dynamic model. All changes in income per capita in (13) are manifested in changes in the home trade share as in ACR. In our model, the ACR formula has to be modified to account for the fact that capital is endogenous and depends on trade frictions; the modification is similar to Mutreja, Ravikumar, and Sposi (2014) and Anderson, Larch, and Yotov (2015).

Equation (13) allows us to decompose the relative importance of changes in TFP and changes in capital in accounting for the steady-state welfare gains. The log-change in welfare that corresponds to a log-change in the home trade share is

\[
\frac{\partial \ln(y_i)}{\partial \ln(\pi_{ii})} = - \left( \frac{1 - \nu_c}{\theta \nu_m} + \frac{\alpha (1 - \nu_x)}{(1 - \alpha) \theta \nu_m} \right)\tag{14}
\]

Based on our calibration, the first term equals 0.08, while the second term equals 0.30. That is, 79 percent of the change in income per capita across steady states can be attributed to...
change in capital and the remaining 21 percent to change in TFP. This decomposition is constant across countries in our model since the elasticities ($\theta, \alpha, \nu_c, \nu_m, \nu_x$) are all constant across countries. This does not imply that the change in income is the same across countries (see Figure 3a), only that the relative contributions from TFP and capital are the same. Furthermore, the relative contributions do not depend on the details on the counterfactual increases or reductions in trade costs.

Figure 3: Distribution of gains from trade

**Dynamic gains** Dynamic gains also vary substantially across countries, ranging from 11 percent for the United States, to 56 percent for Belize, with the median country (Greece) being 32 percent (Figure 3a). The gains are systematically smaller for large, developed countries, and countries with smaller trade frictions. All of these findings are consistent with the existing literature (Waugh and Ravikumar, 2016; Waugh, 2010). Furthermore, the magnitude of our changes in welfare is similar to that in Desmet, Nagy, and Rossi-Hansberg (2015) who consider a counterfactual increase of 40 percent in trade costs in a model of migration and trade, and find that welfare decreases by an average of 39 percent.

Figure 3a shows that the dynamic gains are smaller. The average ratio of dynamic gains to steady-state gains is 60.2 percent and varies from a minimum of 60.1 percent to a maximum of 60.5 percent (see Figure 3b). This result is not specific to the magnitude of the trade liberalization: The ratio of dynamic to steady-state gains is about 60 percent in other
counterfactuals where trade frictions are uniformly reduced across countries.

The ratio of roughly 60 percent is a result of (i) the initial change in consumption and (ii) the rate at which consumption converges to the new steady state. If consumption jumped to its new steady-state level on impact, then the ratio would be close to 100 percent. If instead consumption declined significantly in the beginning and then converged to the new steady state slowly, then the ratio would be closer to 0 percent since there would be consumption losses in earlier periods, while higher levels of future consumption would be discounted. In our model, the consumption dynamics look similar across countries, except for scale. Figure 4 illustrates the consumption dynamics for five countries.

**Figure 4: Consumption Dynamics**

![Consumption Dynamics Graph](image)

Notes: Year 0 is the initial steady state and year 1 is the period of liberalization. Each path is for consumption per capita relative to the U.S. per capita consumption in the initial steady state.

**Mechanics** Trade liberalization increases each country’s output, making more consumption and investment feasible. The immediate increase in output is driven by an immediate increase in TFP; capital does not change on impact. Optimal allocation of the higher output to consumption and investment determines the dynamics and is governed by the relative price of investment and the return to capital, as revealed by the Euler equation (4).

Figure 5 shows the transition paths for the relative price of investment for the country
with the median gain. The transition paths for other countries are similar, but differ in magnitudes: Belize is at one extreme and the U.S. is at the other.

Figure 5: Transition path for the relative price in the median country

![Transition path for relative price](chart.png)

Notes: The country with the median dynamic gain is Greece. Variables are indexed to 1 in the initial steady state. Year 0 is the initial steady state and year 1 is the period of liberalization.

The relative price differences across countries are large in our calibrated steady state and in the data: The relative price in Belize is more than twice that in the U.S. Trade liberalization reduces these differences: The relative price in Belize is only 10 percent higher than that in the U.S. after the liberalization. The reason for the decline in the relative price of investment is that trade liberalization decreases the price of traded intermediates and since intermediates are used more intensively in the production of investment goods than in consumption goods \((\nu_x < \nu_c)\), the price of investment goods falls relative to that of consumption goods.\(^5\) The decline in the relative price of investment implies the household can increase investment by a larger proportion than the increase in output without giving up consumption.

\(^5\) Using input-output data for 40 countries we find that there is indeed variation in \(\nu_c\) and \(\nu_x\). In every one of these countries \(\nu_x - \nu_c < 0\), with a range from -0.35 to -0.71. However, we assume that both \(\nu_c\) and \(\nu_x\) are constant across countries since (i) we do not have data on these shares for our sample of 93 countries and (ii) country-specific values for these parameters add noise to the channels that we explore. We should note that allowing for these shares to differ across countries is straightforward with our solution algorithm.
If $\nu_x = \nu_c$, the relative price of investment would remain constant and would not respond to changes in trade frictions. When we calibrate the model by setting $A_{xi} = A_{ci}$ to match the price of GDP relative to intermediates in country $i$ and $\nu_x = \nu_c = 0.88$ to satisfy the national income accounts equation (8), the dynamic gains are about half of our baseline gains. Figure 6 illustrates the cross-country distribution of gains for our baseline as well as the case where $\nu_x = \nu_c$.

Figure 6: Distribution of gains from trade

![Graph showing distribution of gains from trade](image)

Figure 7 illustrates the consumption paths for the median gain country (Greece). When the relative price of investment remains invariant to the changes in trade frictions, the path converges to a lower level of steady-state consumption relative to our baseline. As a result, the steady-state gains are less than 40 percent of the corresponding gains in the baseline. The lower steady state gain is despite the fact that the percent decline in home trade share is almost the same in our baseline and in the case when $\nu_x = \nu_c$. In our baseline, equation (5) implies that for a one percent decline in the home trade share the relative price decreases by roughly 0.5 percent. Since the nominal investment rate in steady state is a constant unaffected by country-specific distortions, the real investment rate increases by 0.5 percent yielding a higher capital stock. This channel is completely absent when $\nu_x = \nu_c$.

Country $i$’s return to capital on the transition path, $\left(1 + \frac{r_{t+1}}{P_{x,t+1}} - \delta\right)$, is higher than its
Notes: The country with the median dynamic gain is Greece. Variables are indexed to 1 in the initial steady state. Year 0 is the initial steady state and year 1 is the period of liberalization.

steady-state return, $1/\beta$ (see figure 8). This is because, following the trade liberalization, measured TFP is higher. With the higher return, households invest more and the capital-labor ratio increases along the transition. This drives the return back to its initial steady-state level.

As capital accumulates on the transition path, output increases. Recall that the increase in output on impact is entirely due to TFP, whereas the increase in output after the initial period is driven entirely by capital accumulation. With higher output, both consumption and investment increase and settle to the new, higher steady-state levels.

With balanced trade in each period, the return to capital is not equalized across countries on the transition path. The returns are equal in steady state since the return is pinned down by the discount factor, which is the same across countries.

Relation to static models The dynamic gains from trade are quantitatively higher than those in a model where factors of production are held fixed. In a static model, the gains from trade are driven entirely by changes in TFP. In our dynamic model, TFP jumps immediately to (almost) its new steady-state level (see Figure 9) and the change in TFP is
Notes: The country with the median dynamic gain is Greece. Variables are indexed to 1 in the initial steady state. Year 0 is the initial steady state and year 1 is the period of liberalization.

exactly the same as that in a static model. Based on our decomposition in equation (13), the static gains are 21 percent of the steady-state gains. We also know from our counterfactual exercise that the dynamic gains are around 60 percent of the steady-state gains. Therefore, the dynamic gains are almost three times as large as the static gains.

**A short cut to computing the transition paths** Almost all of the changes in home trade shares in response to trade liberalization are immediate. In other words, almost all of the changes in measured TFP take place at the time of the liberalization. This immediate change implies that one can compute the transition paths in our model by solving the transition paths for 93 *closed* economies as follows. We compute the home trade share in the counterfactual steady state for each country; this can be done without solving for the transition paths. We use the home trade shares to compute the measured openness-adjusted productivity, $\tilde{T}_{mi} = \frac{T_{mi}}{\pi_i}$, in each country. We endow each country with $\tilde{T}_{mi}$ and compute its transition path assuming it is closed. This transition path is practically identical to the one in our open economy model. This procedure does not apply in a world with trade imbalances since the home trade share and the measured TFP adjust gradually over time (see Section
Figure 9: Transition path for TFP in the median country

Notes: The country with the median dynamic gain is Greece. TFP is indexed to 1 in the initial steady state. Year 0 is the initial steady state and year 1 is the period of liberalization.

4.3 Comparison with the sufficient statistics approach

In steady state, using equation (13), the change in welfare for country $i$ is given by

$$\dot{y}_i \propto \left( \hat{\pi}_{ii} \right)^{\frac{1-\nu_x}{\theta \sigma_m}} \left( \hat{\pi}_{ii} \right)^{\alpha(1-\nu_k)(1-\alpha)\theta \sigma_m} ,$$  \hspace{1cm} (15)

where the hat denotes the ratio of the variable’s value in the counterfactual to its value in the initial steady state. Equation (15) implies that the change in country $i$’s home trade share is sufficient to pin down the change in the country’s welfare across steady states.

Equation (15) is similar to the sufficient statistic formula used by ACR except we have an additional term that accounts for the change in capital. As in ACR, computing the welfare cost of moving to autarky is straightforward since the home trade share in the initial steady state is the observed home trade share and the home trade share under autarky is 1. Thus, there is no need to solve the model for the counterfactual home trade share and the observed
home trade share is sufficient to describe the steady-state welfare cost of autarky.

Computing the gains from moving to a frictionless trade world requires computing the counterfactual value of the home trade. In a static model, Waugh and Ravikumar (2016) provide a sufficient statistics formula that describes the gains. In their formula, cross-country observations on home trade shares and income are sufficient to compute the welfare gains.

Aside from the extreme cases of autarky and frictionless trade, computing changes in welfare across steady states involves solving the entire model for each counterfactual reduction in trade frictions.

In our dynamic model, computing the welfare gain along the transition path by applying equation (15) period by period is invalid. First, along the transition, consumption is not proportional to income. For instance, consumption in the median-gain country grows by 4.7 percent between periods 2 and 3, while income grows by only 3.4 percent. Second, changes in the home trade share between any two periods does not describe changes in income.

Figure 10 plots the transition path for the home trade share, consumption and income in our model for the median-gain country. The home trade share jumps on impact to the new steady state level and remains constant thereafter (see Figure 10a). Income growth, however, remains above 1 percent even after 12 periods (see Figure 10b).

Figure 10: Transition for home trade share, consumption, and income in the median country

\[\text{(a) Home trade share}\]

\[\text{(b) Consumption and income}\]

Notes: The country with the median dynamic gain is Greece. Variables are indexed to 1 in the initial steady state. Year 0 is the initial steady state and year 1 is the period of liberalization.
5 Trade imbalances

In our model with balanced trade households cannot borrow from or lend to other countries. Without this avenue to smooth consumption, the welfare gains from trade reported in Section 4 could thus be an underestimate.

We introduce trade imbalances by allowing each country to buy and sell one-period bonds. The bonds yield a risk-free world interest rate $q_t$ in period $t$. The household’s budget constraint becomes

$$P_{cit}C_{it} + P_{rit}X_{it} + B_{it} = w_{it}L_{it} + r_{it}K_{it} + q_tA_{it},$$

where $B_{it}$ denotes net purchases of one-period bonds or the current account balance and $A_{it}$ denotes the net foreign asset (NFA) position. NFAs accumulate according to

$$A_{it+1} = A_{it} + B_{it}.$$

We assume that all debts are eventually paid off. Countries that borrow in the short run to finance trade deficits will have to pay off the debts in the long run via trade surpluses.

In addition to endogenous trade imbalances, we introduce in adjustment costs to capital accumulation as in Eaton, Kortum, Neiman, and Romalis (2016). Without adjustment costs, the household’s choice of bonds and investment goods in its portfolio decision problem is indeterminate. With an adjustment cost to capital accumulation, the household chooses a unique portfolio. We specify the adjustment costs as follows:

$$K_{it+1} = (1 - \delta)K_{it} + \chi X_{it}^{\mu} K_{it}^{1-\mu},$$

where $\chi$ denotes the efficiency of investment and $\mu$ governs the adjustment cost. For convenience, we work with investment:

$$X_{it} = \Phi(K_{it+1}, K_{it}) = \left(\frac{1}{\chi}\right)^{\frac{1}{\mu}} (K_{it+1} - (1 - \delta)K_{it})^{\frac{1}{\mu}} K_{it}^{\frac{\mu-1}{\mu}}.$$}

This technology implies that from each household’s perspective, the rate of return on investment depends on the quantity of investment.
The dynamics are now governed by two intertemporal Euler equations:

\[
\frac{C_{it+1}}{C_{it}} = \beta^\sigma \left( \frac{1 + q_{t+1}}{P_{cit+1}/P_{cit}} \right)^\sigma
\]

and

\[
\frac{C_{it+1}}{C_{it}} = \beta^\sigma \left( \frac{\frac{r_{it+1}}{P_{xit+1}} - \Phi_2(K_{it+2}, K_{it+1})}{\Phi_1(K_{it+1}, K_{it})} \right)^\sigma \left( \frac{P_{xit+1}/P_{cit+1}}{P_{xit}/P_{cit}} \right)^\sigma,
\]

where \(\Phi_1(\cdot, \cdot)\) and \(\Phi_2(\cdot, \cdot)\) denote the first derivatives of the adjustment-cost function with respect to the first and second arguments, respectively:

\[
\Phi_1(K', K) = \left( \frac{1}{\chi} \right) \left( \frac{1}{\mu} \right) \left( \frac{K'}{K} - (1 - \delta) \right)^{\frac{1 - \mu}{\mu}}
\]

\[
\Phi_2(K', K) = \left( \frac{1}{\chi} \right) \left( \frac{1}{\mu} \right) \left( \frac{K'}{K} - (1 - \delta) \right)^{\frac{1 - \mu}{\mu}} \left( \frac{(\mu - 1)K'}{K} - \mu(1 - \delta) \right).
\]

To close the model, we require that the current account balance equals net exports plus net-foreign income on assets in each country:

\[
B_{it} = P_{mit}(Y_{mit} - M_{it}) + q_tA_{it}.
\]

### 5.1 Solving the model with trade imbalances

As in the balanced-trade model, to compute the transition path we begin by reducing the infinite horizon problem down to a finite time model with \(t = 1, \ldots, T\) periods. In the model with balanced trade we solved the initial steady state and the counterfactual steady state, and then computed the transition path between these two steady states. In the model with trade imbalances, the transition path and the steady state are determined jointly, so we have to modify our computational procedure. We proceed as follows.

**Initial steady state** For the initial steady state, we abstract from how the world reached the steady state. We specify the steady-state values for the NFA positions, \(A_{i1}\), for all \(i\). The initial steady state is then characterised by a similar set of equations as in the model with balanced trade (see Table C.1) with a couple of modifications. The steady-state
Euler equation for investment takes into account the adjustment costs:

\[ r_i^* = \left( \frac{\Phi_1^*}{\beta} + \Phi_2^* \right) P_{xit}, \]

where \( \Phi_2^* = \delta - \frac{1}{\beta} \), \( \Phi_1^* = \frac{1}{\beta} \), and \( * \) superscript denotes the steady-state value. The Euler equation for purchases of bonds pins down the world interest rate:

\[ q^* = \frac{1 - \beta}{\beta}. \]

**Counterfactual transition and steady state** The counterfactual steady state is one in which current accounts are balanced in all countries but the countries could have trade imbalances. The steady state depends on the transition path since a country may accumulate assets early on, financed by a trade surplus, but collect income later from the assets and use it to finance a trade deficit. Thus, steady-state trade imbalances and NFA positions depend on what happens along the transition.

To compute the counterfactual transition path and the counterfactual steady state, we assume without loss of generality that the terminal NFA position, \( A_{iT+1} = 0 \), for all \( i \). We compute the sequence of endogenous variables for 150 periods and discard the last 65. In our computations, the model reaches a steady state by period 85, independent of the terminal NFA positions. This is an application of the turnpike theory: Regardless of the terminal value for \( A_{iT+1} \), if \( T \) is large enough, then there is a time \( t^* \) at which the model is sufficiently close to the steady state (i.e., it is on the turnpike). This approach has also been used by Sposi (2012) in a multicountry model with exogenous nominal investment rate and by Kehoe, Ruhl, and Steinberg (2016) in a two-country model with endogenous investment rate.\(^6\) We describe the algorithm to compute the transitional dynamics in Appendix E.

We guess the entire sequences of nominal investment rates, \( \rho_it = \frac{P_{xit}X_{it}}{w_{it}L_{it} + r_{it}K_{it}} \), and wages for every country, and one sequence of world interest rates. Taking the nominal investment rate as given, we iterate over wages and the world interest rate using excess demand equations. Given the wages and the world interest rate, all other prices and trade shares are recovered from first-order conditions and a subset of market clearing conditions. We use deviations from the balance of payments identity—net purchases of bonds (current account) equals net exports plus net foreign income—and trade balance at the world level to update the sequences of wages in every country and the world interest rate at every point in time.

\(^6\)See also Reyes-Heroles (2016) for a multicountry model of trade imbalances without capital.
simultaneously. Once we find sequences that satisfy balance of payments, we check whether
the Euler equation for investment in physical capital is satisfied. We use deviations from the
Euler equation to update the nominal investment rate in every country at every point in time
simultaneously. We continue this procedure until we reach a fixed point in the sequences of
nominal investment rates. Appendix E describes our solution method in more detail.

Again, our approach avoids computing costly gradients. We solve the entire transition
path for our world with 93 countries in about 40 hours on a basic laptop computer.

5.2 Quantitative implications with trade imbalances

We set $\mu = 0.55$ as in Eaton, Kortum, Neiman, and Romalis (2016) and $\chi = \delta^{1-\mu} = 0.28$,
so that there is no cost to maintain the level of capital stock in steady state (i.e., $X = \delta K$).
We assume that trade is balanced and that countries have no assets in the initial period: $A_{i1} = 0$ for every $i$.

We calibrate country-specific parameters using the same targets as in Section 3 for the
same set of 93 countries. The level of capital stock from this steady state serves as the initial
condition for capital before trade liberalization. We evaluate the dynamic responses in every
country to the same trade liberalization as before: a permanent, uniform, 55 percent reduc-
tion in trade frictions. These assumptions help us compare the results in this section to those
for the case of balanced trade and adjustment costs to capital. That is, we add adjustment
costs to our model in Section 2, recalibrate it, and solve it under the counterfactual. This
ensures that the only difference between the two models is the presence or absence of trade
imbalances.

Welfare gains Figure 11 illustrates the cross-country distribution of dynamic gains in
both models. The dynamic gains in the model with trade imbalances differ across coun-
tries by a factor of 5 and are higher relative to the model with balanced trade. However,
quantitatively, the gains practically the same in both models.

Under balanced trade, the rate at which the gains accrue in each country is the same,
but with trade imbalances these rates differ across countries. Small, less-developed countries
front-load their consumption by running trade deficits in the short run while large, developed
countries do the opposite. Under balanced trade, there are persistent differences in the rates
of return along the transition path across countries, ranging from 4 to 7 percent. In the
model with trade imbalances, the bond market ensures that the returns are equalized across
countries at every point in time. This equalization occurs via financial resources flowing
from large, developed countries to small, less-developed countries. Figure 12 illustrates the trade deficits and real rates of return across countries at the time of trade liberalization.

Along the transition, some countries accumulate NFAs by running current account surpluses, while others accumulate liabilities by running current account deficits. To illustrate this point, consider the case of the United States and Belize. Following the trade liberalization, the United States runs a current account surplus (see Figure 13). On impact, the current account surplus exactly equals the trade surplus. In the ensuing periods, the trade surplus shrinks faster than the current account surplus, since the United States earns income from its NFA position. In a matter of 14 periods, the U.S. trade is balanced, meaning that net purchases of bonds (its current account balance) exactly offset its net foreign income. After period 14, the United States continues to run a current account surplus, although its net exports turn negative as its net foreign income exceeds its current account surplus. In the new steady state, the current account is balanced and the U.S. runs a permanent trade deficit that is financed by net foreign income that accrues from its permanent and positive NFA position.

The current account dynamics in Belize are almost the mirror image of those in the United States, where Belize converges to a steady state with permanent net liabilities offset
Notes: Real income on the horizontal axis in panel (a) is the observed total real GDP from PWT 8.1 in 2011.

by a permanent trade surplus. Consumption for Belize in the new steady state is less in the model with trade imbalances than in the model with balanced trade since it front-loads consumption by running a trade surplus in the long run.

The behavior of trade imbalances also reveal a pattern in the rates of capital accumulation from the calibrated steady state to the counterfactual steady state. Figure 14 illustrates that the half-life for capital accumulation varies with trade deficits. Countries with trade deficits in the short run have lower half lives than countries with trade surpluses in the short run. Furthermore, the relationship is nonlinear: The half life increases exponentially with the short-run trade surpluses.

**Evidence**  The model’s qualitative predictions for the dynamics of the investment rate, the relative price of investment, and output are consistent with the data. Wacziarg and Welch (2008) identify dates that correspond to trade liberalization for 118 countries and show that, after such liberalization, the investment rate and GDP increase, as in our model. Furthermore, Wacziarg (2001) finds that the increase in GDP due to trade is primarily through an increase in investment and, hence, capital accumulation. Most of the income gains in our model are due to capital accumulation. Hsieh (2001) provides evidence on the two channels emphasized in our model via a contrast between Argentina and India. During
the 1990s, India reduced barriers to imports that resulted in a 20 percent fall in the relative price of investment between 1990 and 2005. Consequently, the investment rate increased by
a factor of 1.5 during the same time period. After the Great Depression, Argentina restricted imports. From the late 1930s to the late 1940s, the relative price of investment doubled and the investment rate declined.

**Sufficient statistics** Recall from Section 4.3 that our model with balanced trade has a sufficient statistics formula to compute the welfare gains from trade across steady states, but not in the transition. In the model with trade imbalances, the sufficient statistics formula does not yield welfare gains even across steady states. This is because (i) the change in home trade share does not reflect the change in income and (ii) consumption is not proportional to income in the steady state.

Figure 15: Elasticity of income with respect to home trade share

The real income in a country is affected by its steady-state trade imbalance, a phenomenon that is not fully summarized by the home trade share. Given the same drop in home trade share, countries with steady-state trade deficits, such as the United States, have smaller increase in income than countries with steady-state surpluses, such as Belize (see Figure 15). But since Belize has a trade surplus in the new steady state, its change in income overstates its change in consumption and, hence, its steady-state welfare gain.
6 Conclusion

We build a multicountry trade model with capital accumulation to study dynamic welfare gains. We develop an algorithm to efficiently solve for the exact transitional dynamics for a system of second-order, nonlinear difference equations. With balanced trade in each period, the dynamic gains from trade liberalization differ by a factor of 5 across countries. The dynamic gains are 60 percent of the steady-state gains and three times as large as static gains. Almost 80 percent of the gains are due to capital accumulation.

Trade liberalization reduces the relative price of investment, allowing countries to invest more, and therefore attain permanently higher capital-labor ratios. Trade liberalization also increases total factor productivity which increases the rate of return to investment and, hence, the investment rate. As capital accumulates, consumption increases and the welfare gains accrue over time. In a world where the intensity of tradables is the same in consumption goods production and investment goods production, the relative price of investment does not respond to changes in trade frictions and the dynamic gains are only half as large.

We find that the distribution of dynamic gains in a model with endogenous trade imbalances is almost identical to that in the balanced trade model. However, the rate at which the dynamic gains accrue in each country is different from that in the balanced trade model. Small, less-developed countries front-load consumption, while large, developed countries do the opposite. Hence, the short-run gains for small, less-developed countries are larger than those for large, developed countries.

In the model with balanced trade, changes in home trade share are not sufficient to measure welfare gains along the transition path. In the model with trade imbalances, changes in home trade share are not sufficient to welfare gains even across steady states.

We develop a new and fast approach to solving multicountry trade models with a large state space. Our method iterates on prices using excess demand functions and does not involve costly gradient calculations. Our solution method can be used to analyze other types of trade liberalizations such as unilateral or gradual or anticipated reductions in trade frictions and other types of models with multiple sectors.

Appendix

A Equilibrium conditions in the balanced trade model

We describe each equilibrium condition in detail below.

**Household optimization** The representative household chooses a path for consumption that satisfies the following Euler equation:

\[
\frac{C_{it+1}}{C_{it}} = \beta^{\sigma} \left( 1 + \frac{r_{it+1}}{P_{xit+1}} - \delta \right)^{\sigma} \left( \frac{P_{xit+1}/P_{cit+1}}{P_{xit}/P_{cit}} \right)^{\sigma}, \tag{A.1}
\]

Combining the household’s budget constraint and the capital accumulation technology and rearranging, we get:

\[
C_{it} = \left( 1 + \frac{r_{it+1}}{P_{xit+1}} - \delta \right) \left( \frac{P_{xit}}{P_{cit+1}} \right) K_{it} + \left( \frac{w_{it}}{P_{cit+1}} \right) L_{it} - \left( \frac{P_{xit}}{P_{cit+1}} \right) K_{it+1}. \tag{A.2}
\]

**Firm optimization** Markets are perfectly competitive, so firms set prices equal to marginal costs. Denote the price of variety \( v \), produced in country \( j \) and purchased by country \( i \), as \( p_{mij}(v) \). Then \( p_{mij}(v) = p_{mj}(v)d_{ij} \); in country \( j \), \( p_{mj}(v) \) is also the marginal cost of producing variety \( v \). Since country \( i \) purchases each variety from the country that can deliver it at the lowest price, the price in country \( i \) is \( p_{mi}(v) = \min_{j=1,...,I} [p_{mj}(v)d_{mij}] \).

The price of the composite good in country \( i \) at time \( t \) is then

\[
P_{mit} = \gamma \left[ \sum_{j=1}^{I} (u_{jt}d_{ij})^{-\theta} T_{mj} \right]^{-\frac{1}{\theta}}, \tag{A.3}
\]

where \( u_{jt} = \left( \frac{r_{jt}}{\alpha^{\nu_n}} \right)^{\alpha \nu_n} \left( \frac{w_{jt}}{1-\alpha} \right)^{(1-\alpha)\nu_n} \left( \frac{P_{jt}}{1-\nu_n} \right)^{1-\nu_n} \) is the unit cost for a bundle of inputs for intermediate goods producers in country \( n \) at time \( t \).

Next we define total factor usage in the intermediates sector by aggregating across the individual varieties.

\[
K_{mit} = \int_{0}^{1} K_{mit}(v)dv, \quad L_{mit} = \int_{0}^{1} L_{mit}(v)dv, \quad M_{mit} = \int_{0}^{1} M_{mit}(v)dv, \quad Y_{mit} = \int_{0}^{1} Y_{mit}(v)dv.
\]

38
The term $L_{mit}(v)$ denotes the labor used in the production of variety $v$ at time $t$. If country $i$ imports variety $v$ at time $t$, then $L_{mit}(v) = 0$. Hence, $L_{mit}$ is the total labor used in sector $m$ in country $i$ at time $t$. Similarly, $K_{mit}$ is the total capital used, $M_{mit}$ is the total intermediates used as an input, and $Y_{mit}$ is the total output of intermediates.

Cost minimization by firms implies that, within each sector $b \in \{c, m, x\}$, factor expenses exhaust the value of output:

\[
\begin{align*}
    r_{it} K_{bit} &= \alpha \nu_b P_{bit} Y_{bit}, \\
    w_{it} L_{bit} &= (1 - \alpha) \nu_b P_{bit} Y_{bit}, \\
    P_{mit} M_{bit} &= (1 - \nu_b) P_{bit} Y_{bit},
\end{align*}
\]

That is, the fraction $\alpha \nu_b$ of the value of each sector’s production compensates capital services, the fraction $(1 - \alpha) \nu_b$ compensates labor services, and the fraction $1 - \nu_b$ covers the cost of intermediate inputs; there are zero profits.

**Trade flows** The fraction of country $i$’s expenditures allocated to intermediate varieties produced by country $j$ is given by

\[
\pi_{ijt} = \left( \frac{u_{mj} d_{ijt}}{\sum_{j=1}^{T} (u_{mj} d_{ij})^{\theta} T_{mj}} \right), \tag{A.4}
\]

where $u_{mj}$ is the unit cost of intermediate varieties in country $j$.

**Market clearing conditions** The domestic factor market clearing conditions are:

\[
\begin{align*}
    \sum_{b \in \{c, m, x\}} K_{bit} &= K_{it}, \\
    \sum_{b \in \{c, m, x\}} L_{bit} &= L_{i}, \\
    \sum_{b \in \{c, m, x\}} M_{bit} &= M_{it}.
\end{align*}
\]

The first two conditions impose that the capital and labor markets clear in country $i$ at each time $t$. The third condition requires that the use of the composite good equals its supply. Its use consists of demand by firms in each sector. Its supply consists of both domestically and foreign-produced varieties.

The next set of conditions require that goods markets clear.

\[
\begin{align*}
    C_{it} &= Y_{cit}, \\
    X_{it} &= Y_{xit}, \\
    \sum_{j=1}^{I} P_{mj} (M_{cj} + M_{mj} + M_{xj}) \pi_{jlt} &= P_{mit} Y_{mit}.
\end{align*}
\]
The first condition states that the quantity of (nontradable) consumption demanded by the representative household in country $i$ must equal the quantity produced by country $i$. The second condition says the same for the investment good. The third condition imposes that the value of intermediates produced by country $i$ has to be absorbed globally. Recall that $P_{mjt}M_{bjt}$ is the value of intermediate inputs that country $i$ uses in production in sector $b$. The term $\pi_{jit}$ is the fraction of country $j$’s intermediate good expenditures sourced from country $i$. Therefore, $P_{mjt}M_{bjt}\pi_{jit}$ denotes the value of trade flows from country $i$ to $j$.

Finally, we impose an aggregate resource constraint in each country: Net exports equal zero. Equivalently, gross output equals gross absorption:

$$P_{mit}Y_{mit} = P_{mit}M_{it}.$$

## B Data

This section describes the sources of data and any adjustments we make to the data to map it to the model.

### B.1 Production and trade

Mapping the trade dimension of our model to the data requires observations on both production and international trade flows. Our focus is on manufactured intermediate goods. We interpret manufacturing broadly as defined by the International Standard Industrial Classification (ISIC).

We obtain production data from multiple sources. First, we use value added and gross output data from the INDSTAT database, which are reported at the two-digit level using ISIC. The data for countries extend no further than 2010 and not even to 2010 for many countries. We use data on value added output in UN National Accounts Main Aggregates Database (UNNAMAD, http://unstats.un.org/unsd/snaama/Introduction.asp), for 2011. For countries that report both value added and gross output in INDSTAT, we use the ratio in the year closest to 2011 and apply that to the value added from UNNAMAD to recover gross output. For countries with no data on gross output in INDSTAT for any years, we apply the average ratio of value added to gross output across all countries and apply that ratio to the value added figure in UNNAMAD for 2011. In our dataset, the ratio of value added to gross output does not vary significantly over time and is also not correlated with level of development or country size.
Our source for trade data is the UN Comtrade Database (http://comtrade.un.org). Trade is reported for goods using revision 2 Standard International Trade Classification (SITC2) at the four-digit level. We use the correspondence tables created by Affendy, Sim Yee, and Satoru (2010) to map SITC2 to ISIC. We also omit any petroleum-related products from the trade data.

Using the trade and production data, we construct bilateral trade shares for each country pair by following Bernard, Eaton, Jensen, and Kortum (2003) as follows:

$$\pi_{ij} = \frac{X_{ij}}{ABS_{bi}},$$

where $i$ denotes the importer, $j$ denotes the exporter, $X_{ij}$ denotes manufacturing trade flows from $j$ to $i$, and $ABS_i$ denotes country $i$’s absorption defined as gross output less net exports of manufactures.

### B.2 National accounts and price

**GDP and population** We use data on output-side real GDP at current Purchasing Power Parity (2005 U.S. dollars) from PWT 8.1 using the variable $cgdpo$. We use the variable $pop$ from PWT 8.1 to measure the population in each country. The ratio $\frac{cgdpo}{pop}$ corresponds to GDP per capita, $y$, in our model.

In our counterfactuals, we compare changes over time with past trade liberalization episodes using the national accounts from PWT 8.1: $rgdpna$, $rkna$, and $rtfpna$.

We take the price of household consumption and the price of capital formation (both relative to the price of output-side GDP in the United States in constant prices) from PWT 8.1 using variables $plc$ and $pl1$, respectively. These correspond to $P_c$ and $P_x$ in our model.

We construct the price of intermediate goods (manufactures) by combining disaggregate price data from the World Bank’s 2011 International Comparison Program (ICP; http://siteresources.worldbank.org/ICPEXT/Resources/ICP_2011.html). The data have several categories that fall under what we classify as manufactures: “Food and nonalcoholic beverages,” “Alcoholic beverages, tobacco, and narcotics,” “Clothing and footwear,” and “Machinery and equipment.” The ICP reports expenditure data for these categories in both nominal U.S. dollars and real U.S. dollars. The PPP price equals the ratio of nominal expenditures to real expenditures. We compute the PPP for manufactures as a whole of manufactures for each country as the sum of nominal expenditures across categories divided by the sum of real expenditures across categories.
There is one more step before we take these prices to the model. The data correspond to expenditures and thus include additional margins such as distribution. To adjust for this, we first construct a price for distribution services. We assume that the price of distribution services is proportional to the overall price of services in each country and use the same method as above to compute the price across the following categories: “Housing, water, electricity, gas, and other fuels,” “Health,” “Transport,” “Communication,” “Recreation and culture,” “Education,” “Restaurants and hotels,” and “Construction.”

Now that we have the price of services in hand, we strip it away from the price of goods computed above to arrive at a measure of the price of manufactures that better maps to our model. In particular, let $P_d$ denote the price of distribution services and $P_g$ denote the price of goods that includes the distribution margin. We assume that $P_g = P^\psi P_m^{1-\psi}$, where $P_m$ is the price of manufactures. We set $\psi = 0.45$, a value commonly used in the literature.

C Solution algorithm for the balanced trade model

In this Appendix, we describe the algorithm for computing (i) the steady state and (ii) the transition path. Before going further into the algorithms, we introduce some notation. We denote the steady-state objects using the $\star$ as a superscript; that is, $K_i^\star$ is the steady-state stock of capital in country $i$. We denote the vector of capital stocks across countries at time $t$ as $\vec{K}_t = \{K_{it}\}_{i=1}^I$.

C.1 Computing the steady state in the balanced trade model

The steady-state consists of 22 objects: $\vec{w}^\star$, $\vec{r}^\star$, $\vec{P}_c^\star$, $\vec{P}_m^\star$, $\vec{P}_x^\star$, $\vec{C}^\star$, $\vec{X}^\star$, $\vec{K}^\star$, $\vec{M}_c^\star$, $\vec{M}_m^\star$, $\vec{M}_x^\star$, $\vec{\pi}^\star$ (we use the double-arrow notation on $\vec{\pi}^\star$ to indicate that this is an $I \times I$ matrix). Table C.1 provides a list of 23 conditions that these objects must satisfy. One market clearing equation is redundant (condition 12 in our algorithm).

We use the technique from Mutreja, Ravikumar, and Sposi (2014), which builds on Alvarez and Lucas (2007), to solve for the steady state. The idea is to guess a vector of wages, then recover all remaining prices and quantities using optimality conditions and market clearing conditions, excluding the trade balance condition. We then use departures from the trade balance condition in each country to update our wage vector and iterate until we find a wage vector that satisfies the trade balance condition. The following steps outline our procedure in more detail:
Table C.1: Steady-state conditions in the balanced trade model

</tbody>
</table>

Note: $u_{mj}^* = \left( \frac{r_*^j}{\alpha \nu_m} \right) \left( \frac{w_*^j}{1 - \alpha \nu_m} \right) \left( \frac{P_{mi}^*}{1 - \nu_m} \right)^{1 - \nu_m}$. 
(i) We guess a vector of wages $\bar{w} \in \Delta = \{ w \in \mathbb{R}^I_+ : \sum_{i=1}^I w_i \frac{L_i}{1-\alpha} = 1 \}$; that is, with world GDP as the numéraire.

(ii) We compute prices $\bar{P}_c$, $\bar{P}_x$, $\bar{P}_m$, and $\bar{r}$ simultaneously using conditions 16, 17, 18, and 23 in Table C.1. To complete this step, we compute the bilateral trade shares $\bar{\pi}$ using condition 19.

(iii) We compute the aggregate capital stock as $K_i = \frac{\alpha}{1-\alpha} \frac{w_i L_i}{r_i}$, for all $i$, which derives easily from optimality conditions 1 and 4, 2 and 5, and 3 and 6, coupled with market clearing conditions for capital and labor 10 and 11 in Table C.1.

(iv) We use condition 22 to solve for steady-state investment $\bar{X}$. Then we use condition 21 to solve for steady-state consumption $\bar{C}$.

(v) We combine conditions 4 and 13 to solve for $\bar{L}_c$, combine conditions 5 and 14 to solve for $\bar{L}_x$, and use condition 11 to solve for $\bar{L}_m$. Next we combine conditions 1 and 4 to solve for $\bar{K}_c$, combine conditions 2 and 5 to solve for $\bar{K}_M$, and combine conditions 3 and 6 to solve for $\bar{K}_x$. Similarly, we combine conditions 4 and 7 to solve for $\bar{M}_c$, combine conditions 5 and 8 to solve for $\bar{M}_m$, and combine conditions 6 and 9 to solve for $\bar{M}_x$.

(vi) We compute $\bar{Y}_c$ using condition 13, compute $\bar{Y}_m$ using condition 14, and compute $\bar{Y}_x$ using condition 15.

(vii) We compute an excess demand equation as in Alvarez and Lucas (2007) defined as

$$Z_i(\bar{w}) = \frac{P_{mi} Y_{mi} - P_{mi} M_i}{w_i},$$

(the trade deficit relative to the wage). Condition 20 requires that $Z_i(\bar{w}) = 0$ for all $i$. If the excess demand is sufficiently close to 0, then we have a steady state. If not, we update the wage vector using the excess demand as follows:

$$\Lambda_i(\bar{w}) = w_i \left( 1 + \psi \frac{Z_i(\bar{w})}{L_i} \right),$$

which is the updated wage vector, where $\psi$ is chosen to be sufficiently small so that $\Lambda > 0$. Note that $\sum_{i=1}^I \frac{\Lambda_i(\bar{w}) L_i}{1-\alpha} = \sum_{i=1}^I \frac{w_i L_i}{1-\alpha} + \psi \sum_{i=1}^I w_i Z_i(\bar{w})$. As in Alvarez and Lucas (2007), it is easy to show that $\sum_{i=1}^I w_i Z_i(\bar{w}) = 0$ which implies that $\sum_{i=1}^I \frac{\Lambda_i(\bar{w}) L_i}{1-\alpha} = 1$, 44
and hence, $\Lambda : \Delta \rightarrow \Delta$. We return to step (ii) with our updated wage vector and repeat the steps. We iterate through this procedure until the excess demand is sufficiently close to 0. In our computations we find that our preferred convergence metric,

$$\max_{i=1}^I \{|Z_i(\vec{w})|\},$$

converges roughly monotonically towards 0.

### C.2 Computing the transition path in the balanced trade model

The equilibrium transition path consists of 22 objects:

- $\{\vec{w}_t\}_{t=1}^\infty$, $\{\vec{r}_t\}_{t=1}^\infty$, $\{\vec{P}_{ct}\}_{t=1}^\infty$, $\{\vec{P}_{mt}\}_{t=1}^\infty$,
- $\{\vec{P}_{xt}\}_{t=1}^\infty$, $\{\vec{L}_{ct}\}_{t=1}^\infty$, $\{\vec{L}_{mt}\}_{t=1}^\infty$, $\{\vec{L}_{xt}\}_{t=1}^\infty$,
- $\{\vec{K}_{ct}\}_{t=1}^\infty$, $\{\vec{K}_{mt}\}_{t=1}^\infty$, $\{\vec{K}_{xt}\}_{t=1}^\infty$,
- $\vec{\pi}_t \_{t=1}^\infty$ (we use the double-arrow notation on $\vec{\pi}_t$ to indicate that this is an $I \times I$ matrix in each period $t$). Table C.2 provides a list of equilibrium conditions that these objects must satisfy.

We reduce the infinite horizon problem to a finite time problem from $t = 1, \ldots, T$, with $T$ sufficiently large to ensure that the endogenous variables settle to a steady state by $T$. As such, solving the transition first requires solving for the terminal steady state. Also, it requires taking the initial stock of capital as given (either by computing an initial steady state or by taking it from the data, for instance).

Our solution method mimics the idea of that for the steady state but is slightly modified to take into account the dynamic aspect as in Sposi (2012). Basically, we start with an initial guess for the entire sequence of wage and rental rate vectors. From these two objects we can recover all prices and quantities, across countries and throughout time, using optimality conditions and market clearing conditions, excluding the trade balance condition and the market clearing condition for the stock of capital. We then use departures from these two conditions at each point in time and in each country to update the sequence of wages and rental rates. Then we iterate until we find wages and rental rates that satisfy the trade balance condition and the market clearing condition for the stock of capital in each period. We describe our procedure in more detail below.

(i) We guess the entire path for wages $\{\vec{w}_t\}_{t=1}^T$ and rental rates $\{\vec{r}_t\}_{t=2}^T$ across countries, such that $\sum_i w_i L_i = 1 \ (\forall t)$. In period 1, set $\vec{r}_1 = \left(\frac{\alpha}{1-\alpha}\right) \left(\vec{w}_1 \vec{L}\right)$ since the initial stock of capital is predetermined.

(ii) We compute prices $\{\vec{P}_{ct}\}_{t=1}^T$, $\{\vec{P}_{xt}\}_{t=1}^T$, and $\{\vec{P}_{mt}\}_{t=1}^T$ simultaneously using conditions

Note: \( u_{mj} = \left( \frac{r_{jt}}{\alpha \nu_m} \right)^{\alpha \nu_m} \left( \frac{w_{jt}}{(1-\alpha)\nu_m} \right)^{(1-\alpha)\nu_m} \left( \frac{P_{mit}}{1-\nu_m} \right)^{1-\nu_m} \).
16, 17, and 18, in Table C.2. To complete this step, we compute the bilateral trade shares \( \{ \pi_t \}^T_{t=1} \) using condition 19.

(iii) Computing the path for consumption and investment is slightly more involved. This requires solving the intertemporal problem of the household. We do this in three steps. First, we derive the lifetime budget constraint. Second, we derive the fraction of lifetime wealth allocated to consumption at each period \( t \). And third, we recover the sequences for investment and the stock of capital.

**Deriving the lifetime budget constraint** For the representative household in country \( i \), begin with the period budget constraint from condition 21 and combine it with the capital accumulation technology in condition 22 to get

\[
K_{i,t+1} = \left( \frac{w_i}{P_{xit}} \right) L_i + \left( 1 + \frac{r_i}{P_{xit}} - \delta \right) K_{i,t} - \left( \frac{P_{cit}}{P_{xit}} \right) C_{i,t}.
\]

We iterate the period budget constraint forward through time and derive a lifetime budget constraint. At time \( t = 1 \), the stock of capital, \( K_{i1} > 0 \), is given. Next, compute the stock of capital at time \( t = 2 \):

\[
K_{i2} = \left( \frac{w_i}{P_{x1i}} \right) L_i + \left( 1 + \frac{r_{i1}}{P_{x1i}} - \delta \right) K_{i1} - \left( \frac{P_{c1i}}{P_{x1i}} \right) C_{i1}.
\]

Similarly, compute the stock of capital at time \( t = 3 \), but do it so that it is in terms the initial stock of capital.

\[
K_{i3} = \left( \frac{w_i}{P_{x2i}} \right) L_i + \left( 1 + \frac{r_{i2}}{P_{x2i}} - \delta \right) K_{i2} - \left( \frac{P_{c2i}}{P_{x2i}} \right) C_{i2}.
\]

\[
\Rightarrow K_{i3} = \left( \frac{w_i}{P_{x2i}} \right) L_i + \left( 1 + \frac{r_{i2}}{P_{x2i}} - \delta \right) \left( \frac{w_i}{P_{x1i}} \right) L_i + \left( 1 + \frac{r_{i1}}{P_{x1i}} - \delta \right) K_{i1} - \left( 1 + \frac{r_{i2}}{P_{x2i}} - \delta \right) \left( \frac{P_{c1i}}{P_{x1i}} \right) C_{i1} - \left( \frac{P_{c2i}}{P_{x2i}} \right) C_{i2}.
\]
Continue to period 4 in a similar way:

\[ K_{i4} = \left( \frac{w_{i3}}{P_{x3i}} \right) L_i + \left( 1 + \frac{r_{i3}}{P_{x3i}} - \delta \right) K_{i3} - \left( \frac{P_{ci3}}{P_{x3i}} \right) C_{i3} \]

\[ \Rightarrow K_{i4} = \left( \frac{w_{i3}}{P_{x3i}} \right) L_i + \left( 1 + \frac{r_{i3}}{P_{x3i}} - \delta \right) \left( \frac{w_{i2}}{P_{x2i}} \right) L_i \]

\[ + \left( 1 + \frac{r_{i3}}{P_{x3i}} - \delta \right) \left( 1 + \frac{r_{i2}}{P_{x2i}} - \delta \right) \left( \frac{w_{i1}}{P_{x1i}} \right) L_i \]

\[ + \left( 1 + \frac{r_{i3}}{P_{x3i}} - \delta \right) \left( 1 + \frac{r_{i2}}{P_{x2i}} - \delta \right) \left( 1 + \frac{r_{i1}}{P_{x1i}} - \delta \right) K_{i1} \]

\[ - \left( 1 + \frac{r_{i3}}{P_{x3i}} - \delta \right) \left( 1 + \frac{r_{i2}}{P_{x2i}} - \delta \right) \left( \frac{P_{ci1}}{P_{x1i}} \right) C_{i1} \]

\[ - \left( 1 + \frac{r_{i3}}{P_{x3i}} - \delta \right) \left( \frac{P_{ci2}}{P_{x2i}} \right) C_{i2} - \left( \frac{P_{ci3}}{P_{x3i}} \right) C_{i3} \]

Before we continue, it is useful to define \((1 + R_{it}) \equiv \prod_{n=1}^{t} \left( 1 + \frac{r_{in}}{P_{xin}} - \delta \right)\). Then:

\[ \Rightarrow K_{i4} = \frac{(1 + R_{i3}) \left( \frac{w_{i3}}{P_{x3i}} \right) L_i}{(1 + R_{i3})} + \frac{(1 + R_{i3}) \left( \frac{w_{i2}}{P_{x2i}} \right) L_{i2}}{(1 + R_{i2})} + \frac{(1 + R_{i3}) \left( \frac{w_{i1}}{P_{x1i}} \right) L_i}{(1 + R_{i1})} \]

\[ + (1 + R_{i3}) K_{i1} \]

\[ - \frac{(1 + R_{i3}) \left( \frac{P_{ci3}}{P_{x3i}} \right) C_{i3}}{(1 + R_{i3})} - \frac{(1 + R_{i3}) \left( \frac{P_{ci2}}{P_{x2i}} \right) C_{i2}}{(1 + R_{i2})} - \frac{(1 + R_{i3}) \left( \frac{P_{ci1}}{P_{x1i}} \right) C_{i1}}{(1 + R_{i1})} \]

\[ \Rightarrow K_{i4} = \sum_{n=1}^{3} \frac{(1 + R_{i3}) \left( \frac{w_{in}}{P_{xin}} \right) L_{in}}{(1 + R_{in})} - \sum_{n=1}^{3} \frac{(1 + R_{i3}) \left( \frac{P_{xin}}{P_{xin}} \right) C_{in}}{(1 + R_{in})} + (1 + R_{i3}) K_{i1} \]

By induction, for any time \(t\),

\[ K_{it+1} = \sum_{n=1}^{t} \frac{(1 + R_{it}) \left( \frac{w_{in}}{P_{xin}} \right) L_i}{(1 + R_{in})} - \sum_{n=1}^{t} \frac{(1 + R_{it}) \left( \frac{P_{xin}}{P_{xin}} \right) C_{in}}{(1 + R_{in})} + (1 + R_{it}) K_{i1} \]

\[ \Rightarrow K_{it+1} = (1 + R_{it}) \left( \sum_{n=1}^{t} \frac{L_i}{(1 + R_{in})} - \sum_{n=1}^{t} \frac{C_{in}}{(1 + R_{in})} + K_{i1} \right). \]
Finally, observe the previous expression as of $t = T$ and rearrange terms to derive the lifetime budget constraint:

$$
\sum_{n=1}^{T} \frac{P_{cin}C_{in}}{P_{xin}(1 + R_{in})} = \sum_{n=1}^{T} \frac{w_{in}L_{i}}{P_{xin}(1 + R_{in})} + K_{it} - \frac{K_{iT+1}}{(1 + R_{iT})},
$$

(C.1)

In the lifetime budget constraint (C.1), we use $W_i$ to denote the net present value of lifetime wealth in country $i$. We take the capital stock at the end of time, $K_{iT+1}$, as given; in our case, it is the capital stock in the new steady state with $T$ sufficiently large. Note that the terminal condition, $K_{iT+1} = K^*_i$, automatically implies the transversality condition since $\lim_{T \to \infty} (1 + R_{iT}) = \infty$ and $\lim_{T \to \infty} K_{iT+1} = K^*_i$.

**Solving for the path of consumption** Next we compute the consumption expenditures in each period. The Euler equation (condition 23) implies the following relationship between consumption in any two periods $t$ and $n$:

$$
C_{in} = \beta^{\sigma(n-t)} \left( \frac{1 + R_{in}}{1 + R_{it}} \right)^{\sigma} \left( \frac{P_{xin}}{P_{xit}} \right)^{\sigma} \left( \frac{P_{cit}}{P_{cin}} \right)^{\sigma} C_{it}
$$

$$
\Rightarrow \frac{P_{cin}C_{in}}{P_{xin}(1 + R_{in})} = \beta^{\sigma(n-t)} \left( \frac{P_{xin}(1 + R_{in})}{P_{xit}(1 + R_{it})} \right)^{\sigma-1} \left( \frac{P_{cin}}{P_{cit}} \right)^{1-\sigma} \left( \frac{P_{cit}}{P_{cin}} \right)^{1-\sigma}.
$$

Since equation (C.1) implies that $\sum_{n=1}^{T} \frac{P_{cin}C_{in}}{P_{xin}(1 + R_{in})} = W_i$, then we can rearrange the previous expression to obtain

$$
\frac{P_{cit}C_{it}}{P_{xit}(1 + R_{it})} = \left( \frac{\beta^{\sigma t}P_{cit}^{\sigma-1}(1 + R_{it})^{\sigma-1}P_{cin}^{1-\sigma}}{\sum_{n=1}^{T} \beta^{\sigma n}P_{xin}^{\sigma-1}(1 + R_{in})^{\sigma-1}P_{cin}^{1-\sigma}} \right) W_i.
$$

(C.2)

That is, each period the household spends a share $\xi_{it}$ of lifetime wealth on consumption, with $\sum_{t=1}^{T} \xi_{it} = 1$ for all $i$. Note that $\xi_{it}$ depends only on prices.

**Computing investment and the sequence of capital stocks** Given the paths of consumption, we solve for investment $\{\bar{X}_t\}_{t=1}^{T}$ using the period budget constraint in condition 21. The catch here is that there is no restriction that household investment be nonnegative up to this point. Looking ahead, negative investment cannot
satisfy market clearing conditions together with firm optimality conditions. As such, we restrict our attention to transition paths for which investment is always positive, which we find is the case for the equilibrium outcomes in our paper. However, off the equilibrium path, if during the course of the iterations the value of $X_{it}$ is negative, then we set it equal to a small positive number.

The last part of this step is to use condition 22 to compute the path for the stock of capital. $\{\tilde{K}_t\}_{t=2}^{T+1}$. Note that $\tilde{K}_1$ is taken as given and that $\tilde{K}_{T+1}$ is equal to the (computed) terminal steady-state value.

(iv) We combine conditions 4 and 13 to solve for $\{\tilde{L}_{ct}\}_{t=1}^{T}$, combine conditions 5 and 14 to solve for $\{\tilde{L}_{xt}\}_{t=1}^{T}$, and use condition 11 to solve for $\{\tilde{L}_{mt}\}_{t=1}^{T}$. Next we combine conditions 1 and 4 to solve for $\{\tilde{K}_{ct}\}_{t=1}^{T}$, combine conditions 2 and 5 to solve for $\{\tilde{K}_{mt}\}_{t=1}^{T}$, and combine conditions 3 and 6 to solve for $\{\tilde{K}_{xt}\}_{t=1}^{T}$. Similarly, we combine conditions 4 and 7 to solve for $\{\tilde{M}_{ct}\}_{t=1}^{T}$, combine conditions 5 and 8 to solve for $\{\tilde{M}_{mt}\}_{t=1}^{T}$, and combine conditions 6 and 9 to solve for $\{\tilde{M}_{xt}\}_{t=1}^{T}$.

(v) We compute $\{\tilde{Y}_{ct}\}_{t=1}^{T}$ using condition 13, compute $\{\tilde{Y}_{mt}\}_{t=1}^{T}$ using condition 14, and compute $\{\tilde{Y}_{xt}\}_{t=1}^{T}$ using condition 15.

(vi) Until this point, we have imposed all equilibrium conditions except for two: The trade balance condition 20 and the capital market clearing condition 10.

**Trade balance condition** We compute an excess demand equation as in Alvarez and Lucas (2007) defined as

$$Z_w^w \left( \{\tilde{w}_t, \tilde{r}_t\}_{t=1}^{T} \right) = \frac{P_{mit}Y_{mit} - P_{mit}M_{it}}{w_{it}},$$

(the trade deficit relative to the wage). Condition 20 requires that $Z_w^w \left( \{\tilde{w}_t, \tilde{r}_t\}_{t=1}^{T} \right) = 0$ for all $i$. If this is different from zero in some country at some point in time we update the wages as follows:

$$\Lambda^w_i \left( \{\tilde{w}_t, \tilde{r}_t\}_{t=1}^{T} \right) = w_{it} \left( 1 + \psi \frac{Z_w^w \left( \{\tilde{w}_t, \tilde{r}_t\}_{t=1}^{T} \right)}{L_i} \right)$$

is the updated wages, where $\psi$ is chosen to be sufficiently small so that $\Lambda^w_i > 0$. 

50
Market clearing condition for the stock of capital. We compute an excess demand equation

\[ Z_{ri}^r \left( \{ \tilde{w}_t, \tilde{r}_t \}_{t=1}^T \right) = \frac{w_{it}L_i}{1-\alpha} - \frac{r_{it}K_{it}}{\alpha}. \]

Using conditions 1-6, we have imposed that within each sector \( \frac{r_{it}K_{it}}{\alpha} = \frac{w_{it}L_i}{1-\alpha} \). We have also imposed condition 11 that the labor market clears. Hence, the market for capital is in excess demand (i.e., \( \sum_i K_{cit} + K_{mit} + K_{xit} > K_{it} \)) in country \( i \) at time \( t \) if and only if \( \left( \frac{w_{it}L_i}{1-\alpha} \right) > \left( \frac{r_{it}K_{it}}{\alpha} \right) \) (it is in excess supply if and only if the inequality is \(<\)). If this condition does not hold with equality in some country at some point in time, then we update the rental rates as follows. Let

\[ \Lambda_{it}^r \left( \{ \tilde{w}_t, \tilde{r}_t \}_{t=1}^T \right) = \left( \frac{\alpha}{1-\alpha} \right) \left( \frac{L_i}{K_{it}} \right) \Lambda_{it}^w \left( \{ \tilde{w}_t, \tilde{r}_t \}_{t=1}^T \right) \]

be the updated rental rates (taking into account the updated wages).

We return to step (ii) with our updated wages and rental rates and repeat the steps. We iterate through this procedure until the excess demand is sufficiently close to 0. In our computations we find that our preferred convergence metric,

\[ T_{\max}^\text{max} \left\{ \max_{t=1}^T \left\{ \left| Z_{it}^w \left( \{ \tilde{w}_t, \tilde{r}_t \}_{t=1}^T \right) \right| + \left| Z_{it}^r \left( \{ \tilde{w}_t, \tilde{r}_t \}_{t=1}^T \right) \right| \right\} \}, \]

converges roughly monotonically toward zero.

Along the equilibrium transition, \( \sum_i w_{it}L_i + r_{it}K_{it} = 1 \) (\( \forall t \)); that is, we have chosen world GDP as the numéraire at each point in time.

The fact that \( \vec{K}_{T+1} = \vec{K}^* \) at each iteration is a huge benefit of our algorithm compared to a shooting algorithm or algorithms that rely on using the Euler equation for updating. Such algorithms inherit the instability (saddle-path) properties of the Euler equation and generate highly volatile terminal stocks of capital with respect to the initial guess. Instead, we impose the Euler equation and the terminal condition for \( \vec{K}_{T+1} = \vec{K}^* \) at each iteration and use excess demand equations for our updating rules, just as in the computation of static models (e.g., Alvarez and Lucas (2007)). Another advantage of using excess demand iteration is that we do not need to compute gradients to choose step directions or step size, as in the case of nonlinear solvers such as the ones used by Eaton, Kortum, Neiman, and Romalis (2016) and Kehoe, Ruhl, and Steinberg (2016). This saves a tremendous amount of computational time, particularly as the number of countries or the number of time periods
is increased.

\section*{D Derivations of structural relationships}

This Appendix shows the derivations of key structural relationships in the balanced trade model. We refer to Table C.2 for the derivations and omit time subscripts to simplify notation. We begin by deriving an expression for $\frac{w_i}{P_{mi}}$ that will be used repeatedly.

Combining conditions 17 and 19, we obtain

$$\pi_{ii} = \gamma^{-\theta} \left( \frac{u_{mi} T_{mi}}{P_{mi} - \theta} \right).$$

Use the fact that $u_{mi} = B_m r_i \nu_m \left( \frac{(1-\alpha) \nu_m}{\nu_m} \right)$, where $B_m$ is a collection of constants; then rearrange to obtain

$$P_{mi} = \left( \frac{T_{mi}}{\pi_{ii}} \right)^{\frac{1}{\theta}} \left( \frac{r_i}{w_i} \right)^{\alpha \nu_m} \left( \frac{w_i}{P_{mi}} \right)^{\nu_m} P_{mi},$$

$$\Rightarrow \frac{w_i}{P_{mi}} = \left( \frac{T_{mi}}{\pi_{ii}} \right)^{\frac{1}{\theta}} \left( \frac{w_i}{r_i} \right)^{\alpha}.$$

\begin{equation}
(D.1)
\end{equation}

Note that this relationship holds in both the steady state and along the transition.

**Relative prices** We show how to derive the price of consumption relative to intermediates; the relative price of investment is analogous. Begin with condition 16 to obtain

$$P_{ci} = \left( \frac{B_c}{A_{ci}} \right) \left( \frac{r_i}{w_i} \right)^{\alpha \nu_c} \left( \frac{w_i}{P_{mi}} \right)^{\nu_c} P_{mi},$$

where $B_c$ is a collection of constants. Substitute equation (D.1) into the previous expression and rearrange to obtain

$$\frac{P_{ci}}{P_{mi}} = \left( \frac{B_c}{A_{ci}} \right) \left( \frac{T_{mi}}{\pi_{ii}} \right)^{\frac{1}{\theta}} \left( \frac{\nu_c}{\nu_m} \right).$$

\begin{equation}
(D.2)
\end{equation}
Analogously,

\[
\frac{P_{xi}}{P_{mi}} = \left( \frac{B_x}{A_{xi}} \right) \left( \frac{\left( \frac{T_{mi}}{\pi_{xi}} \right)^{\frac{1}{\beta}}}{\gamma B_m} \right)^{\frac{\nu_m}{\nu_x}}.
\]  

(D.3)

Note that these relationships hold in both the steady state and along the transition.

**Capital-labor ratio** We derive a structural relationship for the capital-labor ratio in the steady state only and refer to conditions in Table C.1. Conditions 1-6 together with conditions 10 and 11 imply that

\[
\frac{K_i}{L_i} = \left( \frac{\alpha}{1 - \alpha} \right) \left( \frac{w_i}{r_i} \right).
\]

Using condition 23, we know that

\[
r_i = \left( \frac{1}{\beta} - (1 - \delta) \right) P_{xi},
\]

which, by substituting into the prior expression, implies that

\[
\frac{K_i}{L_i} = \left( \frac{\alpha}{1 - \alpha} \right) \left( \frac{w_i}{r_i} \right) \left( \frac{P_{xi}}{P_{mi}} \right).
\]

which leaves the problem of solving for \( \frac{w_i}{P_{xi}} \). Equations (D.1) and (D.3) imply

\[
\frac{w_i}{P_{xi}} = \left( \frac{w_i}{P_{mi}} \right) \left( \frac{P_{mi}}{P_{xi}} \right) = \left( \frac{A_{xi}}{B_x} \right) \left( \frac{\left( \frac{T_{mi}}{\pi_{xi}} \right)^{\frac{1}{\beta}}}{\gamma B_m} \right)^{\frac{1}{\beta} - (1 - \delta)} \left( \frac{w_i}{r_i} \right)^{\alpha}.
\]

Substituting once more for \( \frac{w_i}{r_i} \) in the previous expression yields

\[
\left( \frac{w_i}{P_{xi}} \right)^{1-\alpha} = \left( \frac{1}{\beta} - (1 - \delta) \right)^{-\alpha} \left( \frac{A_{xi}}{B_x} \right) \left( \frac{\left( \frac{T_{mi}}{\pi_{xi}} \right)^{\frac{1}{\beta}}}{\gamma B_m} \right)^{\frac{1}{\beta} - (1 - \delta)}.
\]
Solve for the aggregate capital-labor ratio
\[
\frac{K_i}{L_i} = \left( \frac{\frac{\alpha}{1-\alpha}}{\left(\frac{1}{\beta} - (1 - \delta)\right)^{-\frac{1}{\alpha}}} \right) \left( \frac{A_{ci}}{B_{ci}} \right)^{\frac{1}{1-\alpha}} \left( \frac{T_{mi}}{\pi_{ii}} \right)^{\frac{1}{\nu_c}} P_{mi}^{\frac{1-\nu_c}{\nu_c}} \gamma B_m^{\frac{1-\nu_c}{\nu_c}} \right) . \tag{D.4}
\]

Note that we invoked steady-state conditions, so this expression does not necessarily hold along the transition path.

**Income per capita** We define (real) income per capita in our model as
\[
y_i = \frac{r_i K_i + w_i L_i}{L_i P_{ci}} .
\]

We invoke conditions from Table C.2 for the remainder of this derivation. Conditions 1-6, 10, and 11 imply that
\[
r_i K_i + w_i L_i = \frac{w_i L_i}{1 - \alpha} \Rightarrow y_i = \left( \frac{1}{1 - \alpha} \right) \left( \frac{w_i}{P_{ci}} \right) .
\]

To solve for \( \frac{w_i}{P_{ci}} \), we use condition 16:
\[
P_{ci} = \frac{B_c}{A_{ci}} \left( \frac{r_i}{w_i} \right)^{\alpha \nu_c} \left( \frac{w_i}{P_{mi}} \right)^{\nu_c} P_{mi} \Rightarrow \frac{P_{ci}}{w_i} = \frac{B_c}{A_{ci}} \left( \frac{r_i}{w_i} \right)^{\alpha \nu_c} \left( \frac{w_i}{P_{mi}} \right)^{\nu_c - 1} .
\]

Substituting equation (D.1) into the previous expression and exploiting the fact that \( \frac{w_i}{r_i} = \left( \frac{1-\alpha}{\alpha} \right) \left( \frac{K_i}{L_i} \right) \) yields
\[
y_i = \left( \frac{1}{1 - \alpha} \right) \left( \frac{w_i}{P_{ci}} \right) = \alpha^{-\alpha} (1 - \alpha)^{\alpha - 1} \left( \frac{A_{ci}}{B_c} \right) \left( \frac{T_{mi}}{\pi_{ii}} \right)^{\frac{1}{\beta}} P_{mi}^{\frac{1-\nu_c}{\nu_c}} \gamma B_m^{\frac{1-\nu_c}{\nu_c}} \left( \frac{K_i}{L_i} \right)^{\alpha} . \tag{D.5}
\]
Note that this expression holds both in the steady state and along the transition path.

The steady-state income per capita can be expressed more fundamentally by invoking equation (D.4) as

\[ y_i = \left( \frac{\left( \frac{1}{\beta} - (1 - \delta) \right)^{-\frac{\alpha}{1-\alpha}}}{1-\alpha} \right) \left( \frac{A_{ci}}{B_c} \right) \left( \frac{A_{xi}}{B_x} \right)^{\frac{\alpha}{1-\alpha}} \left( \frac{T_{mi}}{\pi_{ii}} \right) \left( \frac{\gamma B_m}{\nu_c} \right)^{\frac{i}{\nu}} \left( \frac{\nu_m}{\nu_x} \right)^{1-\nu_m} \right)^{1-\nu_c + \frac{\nu_m}{\nu_x} (1-\nu_x)}. \]  \hspace{1cm} (D.6)

### E  Solution algorithm for the model with endogenous trade imbalances

In this Appendix, we describe the algorithm for computing the transition path in the model with adjustment costs to capital and endogenous trade imbalances. We first make some housekeeping remarks regarding the capital accumulation technology.

We work with investment for convenience, which is given by

\[ X_{it} = \Phi(K_{it+1}, K_{it}) = \left( \frac{1}{\chi} \right)^{\frac{1}{\mu}} (K_{it+1} - \delta K_{it})^{\frac{1}{\mu}} K_{it}^{\frac{\mu-1}{\mu}}. \]

We use the derivatives of the investment function, with respect to future and current capital, as given by

\[ \Phi_1(K', K) = \left( \frac{1}{\chi} \right)^{\frac{1}{\mu}} \left( \frac{1}{\mu} \right) \left( \frac{K'}{K} - \delta \right)^{\frac{1-\mu}{\mu}} \]

\[ \Phi_2(K', K) = \left( \frac{1}{\chi} \right)^{\frac{1}{\mu}} \left( \frac{1}{\mu} \right) \left( \frac{K'}{K} - \delta \right)^{\frac{1-\mu}{\mu}} \left( (\mu - 1) \frac{K'}{K} - \mu(1 - \delta) \right). \]

#### E.1  Computing the steady state with trade imbalances

We compute the initial steady state using the same method as in the balanced trade model, with a modification to condition 23 in Table C.1. In particular, the real rate of return must account for the cost of adjusting the capital stock so that it becomes

\[ r_i = \left( \frac{\Phi_{1i}}{\beta} + \Phi_{2i} \right) P_{xi}. \]
Note that in steady state, when we set $\chi = \delta^{1-\mu}$ so that there are no adjustment costs (i.e., $X_i = \delta K_i$), then $\Phi_1 = \frac{1}{\mu}$ and $\Phi_2 = \delta - \frac{1}{\mu}$.

In general, in models with trade imbalances, the steady state is not independent of the transition path that leads up to that steady state. We treat the initial steady state as independent of the prior transition and compute the transition from that steady state. As a result, the new steady state is determined jointly with the transition path.

### E.2 Computing the transition path with trade imbalances

The equilibrium transition path consists of the following objects: $\{\vec{w}_t\}_{t=1}^T, \{\vec{r}_t\}_{t=1}^T, \{\vec{q}_t\}_{t=1}^T, \{\vec{P}_c\}_{t=1}^T, \{\vec{P}_m\}_{t=1}^T, \{\vec{P}_x\}_{t=1}^T, \{\vec{C}_t\}_{t=1}^T, \{\vec{X}_t\}_{t=1}^T, \{\vec{K}_t\}_{t=1}^{T+1}, \{\vec{A}_t\}_{t=1}^{T+1}, \{\vec{Y}_c\}_{t=1}^T, \{\vec{Y}_m\}_{t=1}^T, \{\vec{Y}_x\}_{t=1}^T, \{\vec{L}_c\}_{t=1}^T, \{\vec{L}_m\}_{t=1}^T, \{\vec{L}_x\}_{t=1}^T, \{\vec{M}_c\}_{t=1}^T, \{\vec{M}_m\}_{t=1}^T, \{\vec{M}_x\}_{t=1}^T, \{\vec{\pi}_t\}_{t=1}^T$ (The double-arrow notation on $\vec{\pi}_t$ is used to indicate that this is an $I \times I$ matrix in each period $t$). Table E.1 provides a list of equilibrium conditions that these objects must satisfy.

In this environment, the world interest rate is strictly nominal. That is, the prices map into current units, as opposed to constant units. In other words, the model can be rewritten so that all prices are quoted in time-1 units (like an Arrow-Debreu world) with the world interest rate of zero and the equilibrium would yield identical quantities. Since our choice of numéraire is world GDP in each period, the world interest rate reflects the relative valuation of world GDP at two points in time. This interpretation helps guide the solution procedure.

The solution procedure boils down to two iterations. First, we guess a set of nominal investment rates at each point in time for every country. Given these investment rates, we adapt the algorithm of Sposi (2012) and iterate on the wages and the world interest rate to pin down the endogenous trade imbalances. Then we go back and update the nominal investment rates that satisfy the Euler equation for the optimal rate of capital accumulation.

To begin, we take the initial capital stock, $K_{i1}$, and the initial NFA position, $A_{i1}$, as given in each country.

(i) Guess a path for nominal investment rates $\{\vec{\rho}_t\}_{t=1}^T$.

(ii) Guess the entire path for wages $\{\vec{w}_t\}_{t=1}^T$ and the world interest rate $\{\vec{q}_t\}_{t=2}^T$, such that $\sum_i \frac{\vec{w}_i L_i}{1-\alpha} = 1 \ (\forall t)$.

(iii) In period 1, set $\vec{r}_1 = \left(\frac{\alpha}{1-\alpha}\right) \left(\frac{\vec{w}_1 L}{K_1}\right)$ since the initial stock of capital is predetermined.

Compute prices $P_{c1}, P_{x1}$, and $P_{m1}$ simultaneously using conditions 16, 17, and 18 in

</table>

Note: The term \( u_{mjt} = \left( \frac{r_{jt}}{\alpha \nu_m} \right)^{(1-\alpha)\nu_m} \left( \frac{w_{jt}}{(1-\alpha)\nu_m} \right)^{(1-\alpha)\nu_m} \left( \frac{P_{mit}}{1-\nu_m} \right)^{1-\nu_m} \).

The function \( \Phi(K_{it+1}, K_{it}) = \left( \frac{1}{\theta} \right)^{\frac{\mu}{\theta}} (K_{it+1} - (1 - \delta) K_{it})^{\frac{1}{\theta} \frac{\mu}{\theta}} \) represents investment. Also, \( \Phi_1(\cdot, \cdot) \) and \( \Phi_2(\cdot, \cdot) \) denote the derivatives with respect to the first and second arguments, respectively.
Table E.1. Solve for investment, $X_1$, using
\[ X_{it} = \rho_{it} \frac{w_{it} L_{it} + r_{it} K_{it}}{P_{xit}}, \]
and then solve for the next-period capital stock, $K_2$, using condition 22. Repeat this set of calculations for period 2, then for period 3, and continue all the way through period $T$. To complete this step, compute the bilateral trade shares $\{\pi_t\}_{t=1}^T$ using condition 19.

(iv) Computing the path for consumption and bond purchases is slightly more involved. This requires solving the intertemporal problem of the household. This is done in three steps. First, we derive the lifetime budget constraint. Second, we derive the fraction of lifetime wealth allocated to consumption in each period. And third, we recover the sequences for bond purchases and the stock of NFAs.

**Deriving the lifetime budget constraint** To begin, (omitting country subscripts for now) use the representative household’s period budget constraint in condition 20 and combine it with the NFA accumulation technology in condition 21 to get
\[ A_{t+1} = r_t K_t + w_t L_t - P_{ct} C_t - P_{xt} X_t + (1 + q_t) A_t. \]
Iterate the period budget constraint forward through time and derive a lifetime budget constraint. At time $t = 1$, the NFA position, $A_{i1}$, is given. Next, compute the NFA position at time $t = 2$:
\[ A_2 = r_1 K_1 + w_1 L_1 - P_{c1} C_1 - P_{x1} X_1 + (1 + q_1) A_1. \]
Similarly, compute the NFA position at time $t = 3$, but do it so that it is in terms of the initial NFA position.
\[ A_3 = r_2 K_2 + w_2 L_2 - P_{c2} C_2 - P_{x2} X_2 + (1 + q_2) A_2 \]
\[ \Rightarrow A_3 = r_2 K_2 + w_2 L_2 - P_{x2} X_2 + (1 + q_2)(r_1 K_1 + w_1 L_1 - P_{x1} X_1) \]
\[ - P_{c2} C_2 - (1 + q_2) P_{c1} C_1 + (1 + q_2)(1 + q_1) A_{i1}. \]
Continue to period 4 in a similar way:

\[ A_4 = r_3 K_3 + w_3 L_3 - P_{x3} C_3 - P_{x3} X_3 + (1 + q_3) A_3 \]

\[ \Rightarrow A_4 = r_3 K_3 + w_3 L_3 - P_{x3} X_3 + (1 + q_3)(r_2 K_2 + w_2 L_2 - P_{x2} X_2) \]

\[ + (1 + q_3)(1 + q_2)(r_1 K_1 + w_1 L_1 - P_{x1} X_1) \]

\[ - P_{x3} C_3 - (1 + q_3)P_{x2} C_2 - (1 + q_3)(1 + q_2)P_{x1} C_1 + (1 + q_3)(1 + q_2)(1 + q_1)A_1. \]

Before proceeding, it will be useful to define \( 1 + Q_t \equiv \prod_{n=1}^{t} (1 + q_n) \):

\[ \Rightarrow A_4 = \frac{(1 + Q_3)(r_3 K_3 + w_3 L_3 - P_{x3} X_3)}{(1 + Q_3)} \]

\[ + \frac{(1 + Q_3)(r_2 K_2 + w_2 L_2 - P_{x2} X_2)}{(1 + Q_2)} \]

\[ + \frac{(1 + Q_3)(r_1 K_1 + w_1 L_1 - P_{x1} X_1)}{(1 + Q_1)} \]

\[ - \frac{(1 + Q_3)P_{x3} C_3}{(1 + Q_3)} \]

\[ - \frac{(1 + Q_3)P_{x2} C_2}{(1 + Q_2)} \]

\[ - \frac{(1 + Q_3)P_{x1} C_1}{(1 + Q_1)} \]

\[ + (1 + Q_3)A_1. \]

By induction, for any time \( t \),

\[ A_{t+1} = \sum_{n=1}^{t} \frac{(1 + Q_n)(r_n K_n + w_n L_n - P_{x n} X_n)}{(1 + Q_n)} - \sum_{n=1}^{t} \frac{(1 + Q_n) P_{x n} C_n}{(1 + Q_n)} + (1 + Q_t)A_1 \]

\[ \Rightarrow A_{t+1} = (1 + Q_t) \left( \sum_{n=1}^{t} \frac{r_n K_n + w_n L_n - P_{x n} X_n}{(1 + Q_n)} - \sum_{n=1}^{t} \frac{P_{x n} C_n}{(1 + Q_n)} + A_1 \right). \]
Finally, observe the previous expression as of \( t = T \) and rearrange terms to derive the lifetime budget constraint:

\[
\sum_{n=1}^{T} \frac{P_n C_n}{(1 + Q_n)} = \sum_{n=1}^{T} \frac{r_n K_n + w_n L_n - P_{xn} X_n}{(1 + Q_n)} + A_1 - \frac{A_{T+1}}{(1 + Q_T)}.
\]  

(E.1)

In the lifetime budget constraint (E.1), \( W \) denotes the net present value of lifetime wealth, taking both the initial and terminal NFA positions as given.

**Solving for the path of consumption**  Next, compute how the net present value of lifetime wealth is optimally allocated over time. The Euler equation (condition 24) implies the following relationship between consumption in any two periods \( t \) and \( n \):

\[
C_n = \left( \frac{L_n}{L_t} \right)^{\beta \sigma (n-t)} \left( \frac{1 + Q_n}{1 + Q_t} \right)^{\sigma} \left( \frac{P_{ct}}{P_{cn}} \right)^{\sigma} C_t
\]

\[
\Rightarrow \frac{P_n C_n}{1 + Q_n} = \left( \frac{L_n}{L_t} \right)^{\beta \sigma (n-t)} \left( \frac{1 + Q_n}{1 + Q_t} \right)^{\sigma-1} \left( \frac{P_{ct}}{P_{cn}} \right)^{\sigma-1} P_t C_t
\]

Since equation (E.1) implies that \( \sum_{n=1}^{T} \frac{P_n C_n}{1 + Q_n} = W \), rearrange the previous expression (putting country subscripts back in) to obtain

\[
\frac{P_{cit} C_{it}}{1 + Q_{it}} = \left( \frac{L_{it}}{L_t} \beta^{\sigma t} (1 + Q_{it})^{\sigma-1} P_{cit}^{1-\sigma} \right) W_i.
\]  

(E.2)

That is, each period the household spends a share \( \xi_{it} \) of lifetime wealth on consumption, with \( \sum_{t=1}^{T} \xi_{it} = 1 \) for all \( i \). Note that \( \xi_{it} \) depends only on prices.

**Computing bond purchases and the NFA positions**  In period 1, take as given consumption spending, investment spending, capital income, labor income, and net income from the initial NFA position to solve for net bond purchases \( \{B_t\}_{t=1}^{T} \) using the period budget constraint in condition 20. Solve for the NFA position in period 2 using condition 21. Then given income and spending in period 2, recover the net bond purchases in period 2 and compute the NFA position for period 3. Continue this process through all points in time.
**Trade balance condition** We impose that net exports equal the current account less net foreign income from asset holding. That is,

\[
Z^w_{it} \left(\{\vec{w}_t, q_t\}_t^{T} \right) = \frac{P_{mit}Y_{mit} - P_{mit}M_{it} - B_{it} + q_tA_{it}}{w_{it}}.
\]

Condition 25 requires that \(Z^w_{it} \left(\{\vec{w}_t, \vec{r}_t\}_t^{T} \right) = 0\) for all \((i, t)\) in equilibrium. If this is different from 0 in some country at some point in time, update the wages as follows.

\[
\Lambda^w_{it} \left(\{\vec{w}_t, q_t\}_t^{T} \right) = w_{it} \left(1 + \psi \frac{Z^w_{it} \left(\{\vec{w}_t, q_t\}_t^{T} \right)}{L_{it}}\right)
\]

is the updated wages, where \(\psi\) is chosen to be sufficiently small so that \(\Lambda^w > 0\).

**Normalizing model units** The next part of this step is updating the equilibrium world interest rate. Recall that the numéraire is world GDP at each point in time:

\[
\sum_{i=1}^{I} (r_{it}K_{it} + w_{it}L_{it}) = 1 \quad (\forall t).
\]

For an arbitrary sequence of \(\{q_{t+1}\}_t^{T}\), this condition need not hold. As such, update the world interest rate as

\[
1 + q_t = \frac{\sum_{i=1}^{I} (r_{it-1}K_{it-1} + \Lambda^w_{it-1}L_{it-1})}{\sum_{i=1}^{I} (r_{it}K_{it} + \Lambda^w_{it}L_{it})} \quad \text{for } t = 2, \ldots, T.
\]

(E.3)

The capital and the rental rate are computed in step (ii), while the wages are the values \(\Lambda^w\) above. The world interest rate in the initial period, \(q_1\), has no influence on the model other than scaling the initial NFA position \(q_1A_{i1}\); that is, it is purely nominal. We set \(q_1 = \frac{1-\beta}{\beta}\) (the interest rate that prevails in a steady state) and choose \(A_{i1}\) so that \(q_1A_{i1}\) matches the desired initial NFA position in current prices.

Having updated the wages and the world interest rate, return to step (ii) and perform each step again. Iterate through this procedure until the excess demand is sufficiently close to 0. In the computations, we find that our preferred convergence metric,

\[
\max_{t=1}^{T} \left\{ \max_{i=1}^{I} \left\{ \left| Z^w_{it} \left(\{\vec{w}_t, q_t\}_t^{T} \right) \right| \right\} \right\},
\]

converges roughly monotonically toward 0. This provides the solution to a “sub-equilibrium” for an exogenously specified nominal investment rate.

(v) The last step of the algorithm is to update the nominal investment rate. Until now, the
Euler equation for investment in capital, condition 23, has not been used. We compute an “Euler equation residual” as

\[ Z_{it}^r \left( \{ \bar{\rho}_t \}_t^{T} \right) = \beta^\sigma \left( \frac{P_{xit+1}}{P_{cit}} \right) ^\sigma \left( \frac{P_{xit+1}/P_{cit+1}}{P_{xit}/P_{cit}} \right) ^\sigma - \left( \frac{C_{it+1}}{C_{it}} \right) . \]  \hspace{1cm} (E.4)

Condition 23 requires that \( Z_{it}^r \left( \{ \bar{\rho}_t \}_t^{T} \right) = 0 \) for all \((i, t)\) in equilibrium. We update the nominal investment rates as

\[ \Lambda_{it}^r \left( \{ \bar{\rho}_t \}_t^{T} \right) = \rho_{it} \left( 1 + \psi Z_{it}^r \left( \{ \bar{\rho}_t \}_t^{T} \right) \right) . \]  \hspace{1cm} (E.5)

To update \( \rho_{iT} \), we need to define \( \Phi_2(K_{iT+2}, K_{iT+1}) \), which is simply its steady-state value, \( \Phi_2^* = \delta - \frac{1}{\mu} \), which serves as a boundary condition for the transition path of capital stocks.

Given the updated sequence of nominal investment rates, return to step (i) and repeat. Continue iterationing until \( \max_{t=1}^T \{ \max_{i=1}^I | Z_{it}^r \left( \{ \bar{\rho}_t \}_t^{T} \right) | \} \) is sufficiently close to 0.

Note: “Dyn” refers to dynamic gains and “SS” refers to steady-state gains. Model 1 is the model with a fixed nominal investment rate and a fixed relative price of investment. Model 2 adds endogenous relative price of investment to model 1. Model 3 adds endogenous nominal investment rate to model 2. Model 4 adds adjustment costs to capital accumulation to model 3. Model 5 adds endogenous trade imbalances to model 4. Steady-state gains are identical in models 2, 3, and 4. The group “Southeast Europe” is an aggregate of Albania, Bosnia and Herzegovina, Croatia, Montenegro, and Serbia.
